The increase of co-ion exclusion from the membrane leads to a higher salt rejection since the latter is determined by rejection of co-ions.

Donnan Equilibrium

Patrick Fievet
Institut UTINAM, University of Franche-Comté, Besançon, France

The Donnan equilibrium describes the distribution of ions between two ionic solutions separated by a semipermeable membrane or boundary. The presence of impermeant ions of one side of the boundary has profound effects on the final distribution of permeant ions as they diffuse to an equilibrium in the solution, which is named after the British chemist Frederick George Donnan (1911, 1995).

To illustrate this phenomenon, let us consider a boundary that initially separates a solution of NaCl (side I) and a solution of NaX (side II), NaCl and NaX being completely dissociated and having the same molar concentrations, and let us assume that the boundary is impermeable to the anion X^- , but completely permeable to both Na^+ and Cl^- ions (Fig. 1a). X^- can be, e.g., an anionic protein inside a cell, the walls of which are impermeable to the protein or surface charged groups (such as, e.g., sulfonic or carboxylic acids) of a synthetic membrane. Since side II does not contain Cl^- ions, Cl^- ions diffuse along the concentration gradient from side I to side II (Fig. 1a). The presence of both Cl^- anions plus impermeable anions on side II makes side II negative relative to side I and establishes an electric potential

Donnan Equilibrium, Fig. 1 Illustration of the establishment of Donnan equilibrium between two solutions (NaCl and NaX) separated by a boundary permeable to K^+ and Cl^- ions but impermeable to the anion X^-

difference at the boundary between sides I and II (Fig. 1b). The development of the negative charge on side II counterbalances the concentration gradient of Cl^- ions and prevents Cl^- concentration from becoming equal on both sides of the membrane. At the same time, the negative charge on side II attracts the positive Na^+ ions to migrate from side I to side II along the electrical gradient. The Na^+ concentration on side II now exceeds that of side I, and Na^+ ions will diffuse back from side II to side I along the concentration gradient (Fig. 1c). At equilibrium, the competing electrical potential and concentration gradients for each ion are in balance and there is no net flow of ions through the membrane (Fig. 1d). Na^+ and Cl^- ions move back and forth between sides I and II in

response to the competing electrochemical gradient so that each side remains electrically neutral due to equal molar concentrations of both cations and anions. Between the two sides, there is unequal distribution of permeant ions with the more total anions on side II. This imbalance in the distribution of permeant ions results in an electrical potential difference between sides I and II, which is called the Donnan potential.

At equilibrium, the electrochemical potentials of the ions on side I and side II are equal, hence:

$$\begin{aligned} \mu_i^{0,I} + RT \ln a_i^I + z_i F \psi^I \\ = \mu_i^{0,II} + RT \ln a_i^{II} + z_i F \psi^{II} \end{aligned} \quad (1)$$

Donnan Equilibrium, Fig. 2 Effect of the initial concentration ratio of NaX (c_2) to NaCl (c_1) on the percentage amount of NaCl diffusing from side I to side II ($100 x/c_1$)

and the distribution ratio of NaCl between sides I and II at equilibrium ($c_1 - x/x$)

where μ_i^0 represents the standard chemical potential of the permeant ion i , a_i is its activity, z_i is its charge number, Ψ is the electric potential, R is the ideal gas constant, T is the temperature, and F is the Faraday constant. The superscripts I and II refer to the side I and side II, respectively.

In the derivation of the electrochemical potential, the difference in pressure between sides I and II is neglected. In the case of a synthetic membrane, this assumption can be justified if its swelling is negligible.

Assuming that the standard chemical potentials on sides I and II are equal, the Donnan potential (defined as the potential difference between the side of the boundary with the impermeant ion and the side with the permeant ions) can be calculated for each permeant ion i as:

$$\Delta\psi_D = \psi^{II} - \psi^I = \frac{RT}{z_i F} \ln \frac{a_i^I}{a_i^{II}} \quad (2)$$

The writing of Eq. 2 for permeant ions Na⁺ and Cl⁻ (assuming sufficiently diluted solutions) and the combination of the two resulting equations lead to the so-called Donnan (or Gibbs-Donnan) equation:

$$[\text{Na}^+]_1 [\text{Cl}^-]_1 = [\text{Na}^+]_2 [\text{Cl}^-]_2 \quad (3)$$

where the square brackets indicate molar concentrations at equilibrium.

It should be noted that Donnan equation Eq. 3 was derived without considering the initial concentrations of NaCl and NaX on sides I and II, respectively.

Figure 2 shows the effect of the initial concentration ratio of NaX (c_2) to NaCl (c_1) on the percentage amount of NaCl diffusing from side I to side II ($100 x/c_1$) and the distribution ratio of NaCl between sides I and II at equilibrium ($c_1 - x/x$). These results are obtained by making the assumption that the liquid volumes on both sides of the membrane are equal.

As can be seen, if the relative concentration of NaX on side II is high enough ($c_2 \gg c_1$), NaCl will be expelled to a large extent from side II to side I and the distribution of NaCl between I and II will be then very unequal, whereas, on the other hand, more NaCl (up to 50 %) will be able to flow from side I to side II with decreasing c_2/c_1 and the distribution ratio of NaCl between I and II will tend then to 1. At equilibrium, the concentration of Cl⁻ ions (i.e., ions with the same charge polarity as the impermeant ions) on side II will be lower than that on side I, whereas the Na⁺ ions (i.e., ions having the charge polarity opposite to that of the

Donnan Equilibrium,

Fig. 3 Effect of the initial concentration ratio of NaX (c_2) to NaCl (c_1) on the concentration ratio of both Cl^- ions ($x/c_1 - x$) and Na^+ ions ($c_2 + x/c_1 - x$) between sides II and I at equilibrium

impermeant ions) will have a higher concentration on side II than on side I (Fig. 3).

Donnan Potential

Patrick Fievet

Institut UTINAM, University of Franche-Comté, Besançon, France

The Donnan potential appears as a result of Donnan equilibrium, which refers to the distribution of ions between two ionic solutions separated

by a semipermeable membrane or boundary. Because of the presence of impermeant ion species on one side of the boundary, the concentrations of permeant ions are not the same on both sides of the boundary. These concentration differences between two solutions lead to chemical potential differences across the boundary and these differences will, on their turn, be compensated by an additional electric potential difference between two solutions. At equilibrium, the electrochemical potentials of permeant ions in two solutions are identical. Assuming their standard chemical potentials are equal, the electric potential difference between two solutions, which is called the Donnan potential ($\Delta\Psi_D$), can then be derived:

$$\Delta\Psi_D = \Psi^{\text{II}} - \Psi^{\text{I}} = \frac{RT}{z_i F} \ln \frac{a_i^{\text{I}}}{a_i^{\text{II}}} \quad (1)$$

with ψ the electric potential, R the ideal gas constant, T the absolute temperature, F the Faraday constant, z_i the charge number of ion i , and a_i its activity. The superscript I and II refer to the solution without impermeant ions and the solution with impermeant ions, respectively.

The impermeant ions may be, e.g., anionic proteins inside a cell whose walls are impermeable or fixed charges of a synthetic membrane.

Equation 1 shows that:

- The Donnan potential will be negative in case of anionic impermeant species (membrane

Donnan Potential,

Fig. 1 Schematic representation of the electric potential distribution in a pore under a concentration difference. $\Delta\psi_D^0$ and $\Delta\psi_D^{\Delta x}$: Donnan potentials at interfaces. $\Delta\psi_{diff}$: diffusion potential. $\Delta\psi_m$: membrane potential

with a negative fixed charge) and positive in case of impermeant cations (membrane with a positive fixed charge).

- The co-ions, i.e., ions with the same charge polarity as the impermeant ions (the latter can be the fixed charges of a synthetic membrane), will be less concentrated on the impermeant ions' side than the other side, whereas the counterions, i.e., ions having the charge polarity opposite to that of the impermeant ions, will be more concentrated there. It results in an unequal distribution of permeant ions (co-ions and counterions) between the two sides.

The Donnan potential is used in the Teorell-Meyer-Sievers (TMS) model (Teorell 1935; Meyer and Sievers 1936) and related models such as the DSP&DE model (Lanteri et al. 2008; Escoda et al. 2010), which notably describe the membrane potential phenomenon. The membrane potential is defined as the electrical potential difference arising through a membrane that separates two solutions of the same electrolyte at the same temperature and hydrostatic pressure but different concentrations. Within the scope of the TMS model (and related models), the membrane potential ($\Delta\psi_m$) is split in two components, namely, the difference between the Donnan potentials at each interface ($\Delta\psi_D^{\Delta x}$ and $\Delta\psi_D^0$: superscripts Δx and 0 refer to the interface between the membrane and the most diluted solution and the interface between the membrane and the most concentrated solution, respectively) and the diffusion potential

($\Delta\psi_{diff}$) arising through the membrane pores (Fig. 1):

$$\Delta\psi_m = \Delta\psi_D^{\Delta x} - \Delta\psi_D^0 + \Delta\psi_{diff} \quad (1)$$

The diffusion potential finds its origin in a difference in transport velocity of cations and anions through the membrane.

Within the scope of the DSP&DE model, ion partitioning at the membrane/solution interfaces is accounted for by means of modified Donnan equations including steric and dielectric effects. The Donnan potential reads as follows:

$$\Delta\psi_D^{int} = \bar{\psi}^{int} - \psi^{int} = \frac{k_B T}{z_i e} \ln \left(\frac{\kappa_i^{int} c_i^{int}}{\bar{c}_i^{int}} \right) \quad (2)$$

with

$$\kappa_i^{int} = \phi_i^{int} \exp(-\Delta W_{i,Born}^{int}) \exp(-\Delta W_{i,image}^{int}) \quad (3)$$

k_B is the Boltzmann constant; T is the absolute temperature; e is the elementary charge; z_i is the charge number of ion i ; ϕ_i^{int} represents the steric partitioning coefficient for ion i , which is defined as the ratio between the available section (i.e., taking into account the zone inside the pore in which the ion center cannot penetrate because of its finite size) and the pore cross-section; and the terms $\Delta W_{i,Born}^{int}$ and $\Delta W_{i,image}^{int}$ denote the increase in the interaction energy due to the Born dielectric effect (Born 1920) and image forces (Dukhin

et al. 1988), respectively, where the prime symbol indicates that both terms are scaled on $k_B T$.

According to Eq. 2, the difference in Donnan potentials, called the Donnan term, is given by (considering $c_i^0 = 2c_i^{\Delta x}$):

$$\Delta\Psi_D^{\Delta x} - \Delta\Psi_D^0 = \frac{k_B T}{z_i e} \ln \left(\frac{\kappa_i^{\Delta x} \bar{c}_i^0}{2\kappa_i^0 \bar{c}_i^{\Delta x}} \right) \quad (4)$$

- For charged membranes, the membrane potential is bound between limiting values corresponding to the Nernst potential at low concentrations and the diffusion potential at high concentrations (Lanteri et al. 2008; Escoda et al. 2010). The Nernst potential corresponds to the asymptotic value of the Donnan term when the co-ion exclusion is total. If the membrane volume charge density is assumed to be independent of the axial position inside pores, the concentration of counterions inside pores is then constant too ($\bar{c}_{\text{counterion}}^0 = \bar{c}_{\text{counterion}}^{\Delta x}$) and Eq. 4 can be rewritten as:

$$\Delta\Psi_D^{\Delta x} - \Delta\Psi_D^0 = \frac{k_B T}{z_{\text{counterion}} e} \ln \left(\frac{\kappa_{\text{counterion}}^{\Delta x}}{2\kappa_{\text{counterion}}^0} \right) \quad (5)$$

Moreover, the steric partitioning coefficients are identical at both interfaces ($\phi_i^0 = \phi_i^{\Delta x} \neq 0$) since the pore radius is assumed to be constant through the membrane. Born effect is also identical at both interfaces ($\Delta W_{i,\text{Born}}^0 = \Delta W_{i,\text{Born}}^{\Delta x} \neq 0$), since it is considered to be independent of the salt concentration. Unlike Born effect, the magnitude of the interaction via image charges depends on concentration. However, there is almost no screening of the image force interaction at low concentrations, and thus, $\Delta W_{i,\text{image}}^0 = \Delta W_{i,\text{image}}^{\Delta x} \neq 0$. It results that $\kappa_{\text{counterion}}^0 = \kappa_{\text{counterion}}^{\Delta x}$. Equation 5 then reduces to:

$$\Delta\Psi_D^{\Delta x} - \Delta\Psi_D^0 = \frac{k_B T}{z_{\text{counterion}} e} \ln(2) \quad (6)$$

which represents the Nernst potential (the value of which is inversely proportional to the charge number of counterions).

In high concentrations, the Donnan contribution tends to zero (the asymptotic value of the membrane potential is then equal to the diffusion potential) due to the screening of both membrane fixed charge density and image force interaction ($\Delta W_{i,\text{Born}}^0 \approx \Delta W_{i,\text{Born}}^{\Delta x} \approx 0$).

- For neutral membranes and when the only exclusion mechanism is the steric exclusion (i.e., $\kappa_i^{\text{int}} = \phi_i^{\text{int}}$) or the Born dielectric exclusion ($\kappa_i^{\text{int}} = \exp(-\Delta W_{i,\text{Born}}^{\text{int}})$) or both ($\kappa_i^{\text{int}} = \phi_i^{\text{int}}, \exp(-\Delta W_{i,\text{Born}}^{\text{int}})$), the Donnan contribution is null irrespective of the concentration. It means that Donnan potentials are equal at both interfaces although each of them differs from zero. Indeed, since cations and anions have usually different sizes, their steric partitioning coefficients are different as well as their terms $\Delta W_{i,\text{Born}}^{\text{int}}$. The smallest ions (e.g., the anions) will be then less excluded than the largest ones (e.g., the cations). Consequently, a slight negative Donnan potential will arise, pulling cation ions into pores and expelling anions to maintain electroneutrality within the membrane. Since only steric effects or only Born dielectric effect or both are considered, one obtains $\kappa_i^0 = \kappa_i^{\Delta x}$. Considering the electroneutrality condition within the membrane, it comes from Eq. 4 that the Donnan potentials are identical at both interfaces, and thus the Donnan contribution to the membrane potential arising through a neutral membrane is null whatever the concentration.

Donnan Steric Pore (DSP) and Dielectric Exclusion (DE) Model

Patrick Fievet

Institut UTINAM, University of Franche-Comté, Besançon, France

The Donnan steric pore (DSP) and dielectric exclusion (DE) model (known as the SEDE model in literature) is a model that describes mass transfer of neutral and charged solutes through *nanofiltration* (NF) membranes (Szymczyk and Fievet 2005). It is based on a macroscopic description of transport and is an extension of the Donnan steric pore model (DSPM) firstly proposed by Bowen and Mukhtar (1996) and then revised in Bowen et al. (1997) and in Bowen and Mohammad (1998). In addition to the steric/electric exclusion mechanisms, the DSP and DE model also includes

dielectric effects. Its main features can be summarized as follows:

- The active layer of the membrane is considered as a charged porous layer and is characterized by means of three adjustable parameters: the average pore radius r_p , the effective membrane thickness δ (including tortuosity or porosity and tortuosity of the active layer depending on the model version), and the volume charge density X (defined as the mole number of fixed charges per unit of pore volume), which is assumed to be constant along the membrane pores. The presence of the coarse-porous support layer is disregarded because it does not affect the retention properties of the membrane.
- The radial variations of both local electric potential and ion concentrations inside the nanopores are neglected. This approximation (called homogeneous approximation) is valid provided the electric charge carried out by the nanopore walls is not too high (Szymczyk et al. 1999).
- Membrane separation is described as being the result of the following steps: first, a distribution of species at the membrane/feed solution interface, followed by solute transport through the pores, and finally a distribution of species at the membrane/permeate interface (Fig. 1).
- The solute transport is based on the extended Nernst–Planck (ENP) equation, which describes transport in terms of diffusion, migration (in the case of ions only), and convection. It is modified by hydrodynamic coefficients ($K_{i,c}$ and $K_{i,d}$) accounting for the effect of finite pore size on the various components of the transport and reads as follows:

$$j_i = -K_{i,d}D_{i,\infty} \frac{d\bar{c}_i}{dx} - \frac{z_i\bar{c}_iK_{i,d}D_{i,\infty}F}{RT} \frac{d\psi}{dx} + K_{i,c}\bar{c}_iV \quad (1)$$

Note for editors: The model developed by Bandini and Vezzani is known as the DSP and DE model. However, their model considers dielectric exclusion in terms of the only image force contribution. My suggestion, therefore, would be to replace the topic title “Donnan Steric Pore (DSP) and Dielectric Exclusion (DE) Model” by the title “SEDE (Steric, Electric, and Dielectric Exclusion) Model,” which includes dielectric exclusion in terms of both Born dielectric effect and image force contribution. It would avoid confusion. Indeed, I wrote this topic by considering my model, namely, the SEDE model, which was developed by Szymczyk and me. However, as requested by the editors, I did use the term DSP and DE in the text below.

- where j_i is the molar flux of specie i through the pores; $D_{i,\infty}$ its diffusivity in the external solution (value at infinite dilution); $\bar{c}_i$ its

Donnan Steric Pore (DSP) and Dielectric Exclusion (DE) Model, Fig. 1 Schematic representation of a pore separating a feed solution (*high-pressure side*) from a permeate (*low-pressure side*) and concentration and

electric potential profiles. Mono-monovalent salt and negatively charged membrane ($X < 0$). $\Delta\psi_D^{\text{int}}$: Donnan potential (superscript int stands for 0 or δ)

concentration inside the pores at the x position along the pore; z_i its charge number; ψ and V are the local electric potential and the solvent velocity inside the pores, respectively; R the ideal gas constant; T the absolute temperature; and F the Faraday constant.

Hydrodynamic coefficients $K_{i,c}$ and $K_{i,d}$ depend on the solute to pore size ratio, λ_i , defined as $\lambda_i = r_{i,\text{Stokes}}/r_p$ where $r_{i,\text{Stokes}}$ is the Stokes radius of the solute which is calculated using the well-known Stokes–Einstein relation:

$$r_{i,\text{Stokes}} = \frac{k_B T}{6\pi\eta D_{i,\infty}} \quad (2)$$

with k_B the Boltzmann constant and η the solvent viscosity.

The meaning and relevance of hindrance factors ($K_{i,c}$ and $K_{i,d}$) have been widely documented by Deen (Deen 1987) as well as by many other authors (Mason et al. 1980; Deen et al. 1980; Nakao and Kimura 1982; Bowen and Sharif 1994).

- The partition coefficient of a solute i at the membrane/external solution interfaces (defined as $\bar{c}_i^{\text{int}}/c_i^{\text{int}}$), which is derived by assuming local thermodynamic equilibrium, is given by:

$$\begin{aligned} \Gamma_i^{\text{int}} &= \frac{\bar{c}_i^{\text{int}}}{c_i^{\text{int}}} \\ &= \Phi_i^{\text{int}} \exp\left(-\frac{z_i e}{k_B T} \Delta\psi_D^{\text{int}}\right) \\ &\quad \exp\left(-\Delta W_{i,\text{Born}}^{\text{int}}\right) \exp\left(-\Delta W_{i,\text{image}}^{\text{int}}\right) \end{aligned} \quad (3)$$

where the superscript int stands for 0 or δ depending on the interface that is considered, the symbol Δ denotes a variation with respect to external solutions, and e is the elementary charge.

The first term on the r.h.s. represents the contribution of the steric exclusion, Φ_i being the steric partitioning coefficient for solute i , which is defined as the ratio between the available section (i.e., taking into account the zone inside the pore in which the ion center cannot penetrate because of its finite size) and the pore cross section (Fig. 2). The steric partitioning coefficient is bounded between 0 and 1, $\Phi_i^{\text{int}} = 1$ for point solutes, whereas $\Phi_i^{\text{int}} = 0$ for solutes larger than the pore. It should be noted that for a neutral solute, the partition coefficient is written as: $\Gamma_i^{\text{int}} = \Phi_i^{\text{int}}$ (due to its zero charge).

$\Delta\psi_D^{\text{int}}$ is the *Donnan potential* involved in the electric exclusion mechanism (Fig. 1). By definition, it has the same sign as the membrane charge. As shown by the second term on the r.h.s. of Eq. 3, the *Donnan potential* is repulsive for co-ions

Donnan Steric Pore (DSP) and Dielectric Exclusion (DE) Model, Fig. 2 Schematic representation of available pore area for transport in a cylindrical (a) and slit-like (b) pore. Φ_i : steric partitioning coefficient; $\lambda_i = r_{i, \text{Stokes}}/r_p$

(i.e., ions having the same charge polarity as the membrane) and attractive for counterions (i.e., ions with the charge polarity opposite to that of the membrane).

Finally, the terms $\Delta W_{i, \text{Born}}^{\text{int}}$ and $\Delta W_{i, \text{image}}^{\text{int}}$ denote the increase in the interaction energy (scaled on $k_B T$) of ion i due to the Born and image force dielectric effects, respectively.

The Born dielectric effect is connected with the lowering of the dielectric constant of the solution inside pores ϵ_p (with respect to the corresponding value in the external bulk solution ϵ_b) caused by an alteration of the solvent structure when it is confined in nanodimensional pores. The variation of the interaction energy resulting from the Born effect is given by:

$$\Delta W_{i, \text{Born}}^{\text{int}} = \frac{(z_i e)^2}{8\pi\epsilon_0 k_B T r_{i, \text{cav}}} \left(\frac{1}{\epsilon_p} - \frac{1}{\epsilon_b} \right) \quad (4)$$

where ϵ_0 is the vacuum permittivity and $r_{i, \text{cav}}$ is the cavity radius of ion i .

Equation 4 is similar to the relation derived in the original Born model (Born 1920) for ion-solvent interactions except that the radius of the cavity formed by the ion i in the solvent ($r_{i, \text{cav}}$) is used here (Rashin and Honig 1985; Hyun and Ichiye 1997; Qiu et al. 1997) instead of the ionic radius as stated in the original Born model (which is known to overestimate solvation enthalpies, especially for cations).

As shown by Eq. 4, the partition due to the Born DE is unfavorable for any ion, independently of the ion polarity (provided $\epsilon_p < \epsilon_b$), and

multivalent ions are more strongly rejected than monovalent ones. Moreover, the Born effect does not depend on pore size and geometry.

The interaction free energy of an ion inside a pore of nanometric dimensions is also affected by the interaction of the ion with the polarization charge induced by the ion itself at the interface between the membrane matrix and the solution inside the pore (Parsegian 1969; Dresner 1974; Glueckauf 1976). This phenomenon results from the difference in dielectric constants between the membrane and the solution and is usually described as the production of image forces (Dukhin et al. 1988) since the interaction between the ion and the polarized interface is formally equivalent to the interaction with a fictitious image charge located at the other side of the interface at the same distance from it as the ion (Fig. 3). This topic has been reviewed recently by Yaroshchuk (2000) who derived approximate expressions for the interaction energy in pores of cylindrical and slit-like geometries. These equations, which are complex, account for the screening of the interaction between the ion and the polarized interface by the membrane fixed charge and the ionic atmosphere as well.

Like the Born effect, this dielectric effect is also controlled by the square of the ion charge. Consequently, it does not differentiate (qualitatively) between co-ions and counterions (unlike the Donnan exclusion which repels co-ions but attracts counterions), and both co-ions and counterions are excluded from the membrane pores provided $\epsilon_m < \epsilon_p$.

Donnan Steric Pore (DSP) and Dielectric Exclusion (DE) Model, Fig. 3 Schematic representation of the interaction of ions with their polarization charge induced by the ions themselves at the interface between the solution inside the pore and the membrane matrix. Image charges can be used to visualize the force arising from the dielectric

discontinuities. It should be noted that the physical effect is the induced polarization charges at the interface whereas the image charge is just a tool to construct an equivalent system where the net interaction is the same (Jonssön and Wennerström 1983)

Last, it should be noted that DE (Born and image forces) plays a relevant role even in the case of uncharged membranes for which Donnan exclusion is zero.

Dope Solution

Department of Applied Physics, Universidad Complutense de Madrid, Madrid, Spain

Dope solution is a homogeneous thermodynamically stable polymer solution formed by a polymer or a copolymer, solvent or a solvent mixture, and/or additive(s) (i.e., the additive can be a second polymer, a non-solvent, organic or inorganic particles of different sizes, etc.). It is also possible to add a non-solvent to the polymer solution to such an extent that all the components are still miscible. In this case, care must be taken because demixing may occur by the addition of the non-solvent to the polymer solution so that it becomes thermodynamically unstable. Sometimes nanoparticles or nanotubes are dispersed in the polymer solution.

To prepare a dope solution, the polymer must be soluble in a solvent or a solvent mixture. The solvent has a close solubility parameter with the polymer. The solvent and the non-solvent must be miscible and the viscosity of the dope solution must be high (i.e., more than 100 P).

After preparing the polymer solution, this should be filtered to remove impurities and insoluble contaminants. Subsequently, the resulted dope solution should be degassed before loading into the dope vessel for fabrication of either flat sheet or ► [hollow fiber](#) membranes. The spinning dope suitable for ► [hollow fiber](#) fabrication by dry/wet spinning or wet spinning techniques

generally has a much greater viscosity and elasticity than that used for the fabrication of flat sheet membranes by the phase inversion technique.

The used polymer limits the solvent(s) and the non-solvent(s) that can be used to prepare the dope solution for the phase inversion process. Water is frequently used as a non-solvent. For example, among others, the solvents dimethyl formamide (DMF) and dimethyl acetamide (DMAC) were used to prepare dope solutions from polysulfone, poly(ether sulfone), poly(vinylidene fluoride), polyacrylonitrile, cellulose acetate, polyimide, or poly(ether imide).

To prepare membranes by thermal precipitation, for example, thermally induced phase inversion (TIPS) membranes, the dope solution is a polymer/diluent system adequate to form a homogeneous melt blend, which will be cooled or quenched to induce phase separation (i.e., liquid–liquid phase separation, solid–liquid phase separation, or combined liquid–liquid and solid–liquid phase separation). For TIPS mechanism the diluent should be miscible with the considered polymer at high temperatures, should have a relatively low molecular weight together with a low volatility at high temperatures, and should be thermally stable at high temperatures. For example, the used diluent for poly(vinylidene fluoride), PVDF, is dimethyl phthalate, dioctyl phthalate, dioctyl sebacate, dibutyl phthalate, γ -butyrolactone, propylene carbonate, or dibutyl sebacate.

The parameters affecting the physical and chemical characteristics of the dope solution are the polymer, the solvent(s), the non-solvent additive(s), and their concentrations as well as the temperature. These characteristics affect the structural morphology of the formed flat sheet membranes and hollow fibers. The polymer concentration in the dope solution is one of the relevant factors affecting membrane structure. For example, the increase of the polymer concentration in the dope solution results in a high-volume fraction of polymer and consequently a low porosity and small pore size. A significant reduction of the porosity was observed with increasing PVDF concentration in the spinning dope from 15 to

20 wt% (Wu et al. 2007). However, over this PVDF concentration range, no apparent effect on the mean pore size of the prepared hollow fibers was observed. Fabrication of membranes by the phase inversion technique from dope solutions with a very low polymer concentration is practically impossible. For instance, when the polymer content is less than a threshold value, for example, 10 wt% for PVDF, the resulting membranes become inconsistent and holes start to appear within the membrane (Ortiz de Zárate et al. 1995). In the phase inversion process, non-solvent additive in the dope solution acts as a pore-forming agent improving the permeability of the fabricated phase inversion membrane. In general, when the concentration of the non-solvent additive is increased in the dope solution, the pore size and porosity of the prepared membrane increase (Khayet and Matsuura 2001).

The maximum amount of non-solvent that can be added to a dope solution can be determined from the ternary phase diagram presenting the composition of the polymer, solvent, and the non-solvent. In this case, the dope solution must be in one phase region where all the components are completely miscible with each other. Figure 1 shows an isothermal ternary system (polymer, P ; solvent, S , non-solvent, NS). The pure components (P , S , NS) are localized at the corners of the triangle, and any point within the triangle represents a mixture of all three components. Within a certain compositionally defined range of thermodynamic states, all three components are completely miscible, whereas in a different range, the system decomposes into two distinct phases. The solid black line is the liquid-liquid boundary, called the binodal which separates the miscible region at the left from the immiscible region at the right. The thermodynamic parameter describing the miscibility of two or more components (e.g., polymer and diluent) is the Gibbs free energy of mixing, for which an expression was given by the Flory-Huggins lattice theory (Flory 1965).

During membrane preparation, the dope solution at the left side of the binodal in the P - S axis is immersed in a non-solvent so that the final

Dope Solution, Fig. 1 Schematic phase diagram of an isothermal ternary system (polymer, P ; solvent, S and non-solvent, NS)

composition will be displaced to the right side in the phase diagram toward the P - NS axis. Different composition paths can occur (Khayet and Matsuura 2011). For example, the path (a , b , c , d) starts from a dope solution with a low initial polymer volume fraction on the P - S axis and the ratio of the rate of solvent outflux to that of the non-solvent influx is relatively high. When the dope solution crosses the binodal, two separate phases will begin to form. Those are a polymer-rich phase represented by the upper end of the tie line and a polymer-poor phase represented by the lower end of the tie line. If the amount of the polymer-rich phase is large relative to the amount of the polymer-poor phase, droplets of the latter phase are dispersed in the continuous polymer-rich phase and form pores in the continuous polymer matrix. The obtained final membrane at the P - NS axis is asymmetric (i.e., a dense surface layer at the film/gelation media interface followed by a porous sub-layer). The film composition starts from the point " a ," passes through points " b " and " c " (polymer densification point), and finally reaches the point " d " along the composition path. " b " is the point where the phase separation starts and " c " is the point where the polymer solidification starts to occur. Exchange of solvent and non-solvent will lead to the final formation of the membrane, the porosity of which is determined by the point on the P - NS line (e.g., point " d ") (Khayet and Matsuura 2011).

Department of Chemical Engineering, School of Chemical Engineering and Technology, Xi'an Jiaotong University, Xi'an City, China

Synonyms

Multiple emulsions

Double emulsion is a complex system of an emulsion in an emulsion, where the droplets of the dispersed phase themselves contain even smaller dispersed droplets. An [emulsion](#) is a dispersion of droplets of one liquid in another one with which it is incompletely miscible.

Two main types of double emulsion can be distinguished: water-in-oil-in-water (W/O/W) emulsion, in which a W/O emulsion is dispersed as droplets in an aqueous phase, and oil-in-water-in-oil (O/W/O) emulsion, in which an O/W emulsion is dispersed in an oil phase. W/O/W emulsion is more common than O/W/O emulsion. Double emulsion contains more interface and is even more thermodynamically unstable than single emulsion (Graaf et al. 2005).

Double emulsions have significant potential in many applications since, at least in theory, they

can serve as an entrapping reservoir for active ingredients that can be released from the inner phase to the outer phase by a controlled and a sustained mechanism. The major area of applications concerns the human pharmaceutical field: water-in-oil-in-water (W/O/W) emulsions have been investigated as potential vehicles for various hydrophilic drugs (vaccines, vitamins, enzymes, hormones) which would be then slowly released. Also, double emulsions have promising applications in other fields like the food industry (low calorie products, improved sensoric characteristics, taste masking), cosmetic industry (easily spreadable creams with encapsulated ingredients in both water and oil phases), separation science, and agriculture.

In practice, double emulsions are thermodynamically unstable systems with a strong tendency for coalescence, flocculation, and creaming. Most double emulsions consist of relatively large droplets, cannot withstand storage regimes, and have a strong tendency to release the entrapped matter in an uncontrolled manner. Four possible mechanisms are described for instability of W/O/W emulsion: (1) coalescence of the internal aqueous droplets, (2) coalescence of the oil drops, (3) rupture of the oil film separating the internal and external aqueous phases, and (4) passage of water (and water-soluble material, e.g., a drug) to and from internal droplets through the oil layer (Graaf et al. 2005). Much work has been devoted in the last decade in order to improve the stability of the multiple emulsions and the control of the release rates of the addenda. The most recent achievements are the use of polymeric emulsifiers to improve interface coverage and to better anchor into the dispersed phase and the decrease of droplet size by improving methods of formation (Garti 1997).

Double emulsion is generally prepared in a two-step emulsification process using two surfactants of opposite solubility. To produce O/W/O emulsion, a W/O emulsion is first prepared with a large excess of hydrophobic surfactant (HLB <10), by strong homogenization, to form the smallest possible droplets. In the second step a W/O/W double emulsion is further formed by gentle addition of the W/O (termed inner

emulsion) to water in which a hydrophilic one (HLB >10) has been dissolved (Bibette et al. 1999).

The most important conventional emulsification devices are stirring apparatuses, rotor–stator systems, and high-pressure homogenizers. **Membrane emulsification** is a relatively new method for the production of emulsions that has received increasing attention over the last 15 years. The technique is attractive given the low energy consumption, the better control of droplet size and droplet size distribution and especially the mildness of the process. **Microchannel emulsification** is a novel method for producing monodisperse emulsions. It is even more monodisperse than usually obtained with membrane emulsification (Graaf et al. 2005).

Double Emulsion Production, Membrane Operations for

Na Li

Department of Chemical Engineering, School of Chemical Engineering and Technology, Xi'an Jiaotong University, Xi'an City, China

Double emulsions are emulsions of emulsions. The droplets of the dispersed phase themselves contain even smaller dispersed droplets. Two main types of double emulsions are water-in-oil-in-water (W/O/W) emulsions and oil-in-water-in-oil (O/W/O) emulsions. The former is more common. Double emulsions have shown significant promise in the food industry, cosmetic industry,

pharmacology industry, and other fields like agriculture and separation science.

Double emulsions are usually prepared in a two-step emulsion process. First, internal emulsion (e.g., water-in-oil (W/O)) is designed under high-shear conditions to obtain small droplets. Secondary emulsion step for double emulsion (e.g., water-in-oil-in water (W/O/W)) is carried out with mild shear to avoid rupture of the internal droplets. Usually, the primary step can be produced by conventional method or also by membrane emulsification, while the membrane emulsification is especially suitable for the second emulsification step.

For the conventional emulsification method, the most commonly used devices are rotor–stator systems and high-pressure homogenizers. In rotor–stator systems (i.e., colloid mills), a high shear is generated between a rotor and a stationary smooth, roughened, or grooved surface. Turbulence is the primary cause of fluid disruption leading to the formation of droplets (Graaf et al. 2005). In a high-pressure homogenizer, the droplets are broken up in a nozzle by turbulence and cavitation. This process can be assisted with the use of an ultrasonic or electric fields. Due to their high throughput, rotor–stator systems and high-pressure homogenizers are suitable for large-scale production of emulsions. However, energy requirements of these systems are high because only a small part of the energy input is used for droplet breakup; most of the energy supplied is lost and converted into heat. Furthermore, shear stresses these systems applied may cause loss of functional properties of heat- and shear-sensitive components. In addition, they show poor control over droplet size and distribution.

In order to overcome the problems of traditional emulsification methods, a new technique for making emulsions known as “membrane emulsification” arouses people’s interest. This method involves using a low pressure to force the dispersed phase to permeate into the continuous phase through a membrane which has a uniform pore-size distribution. Droplets grow at pore outlets and then detach when reaching a certain size (Joscelyne and Tragardh 2000). One of the

most significant advantages of membrane emulsification is the low energy consumption. Also the better control of droplet size and distribution and the mildness of the process are highly attractive. Compared to conventional methods, a disadvantage of membrane emulsification is that the flux of the dispersed phase through the membrane is fairly low. However, the flux of dispersed phase could be increased by using a membrane with a low hydraulic resistance (e.g., microsieves).

The commonly used membranes for membrane emulsification are Shirasu porous glass (SPG) membranes, ceramic aluminum oxide (α -Al₂O₃) membranes, α -alumina- and zirconia-coated membranes, macroporous silica glass membranes, micro-fabricated metal membranes, polytetrafluoroethylene (PTFE) membranes, and hydrophobized silicon nitride microsieves.

For membrane emulsification two methods of operation are used: cross-flow membrane emulsification and premix membrane emulsification.

Generally, the important process controlling parameters are membrane pore size, porosity, thickness, and surface type, the velocity of continuous phase, the transmembrane pressure, and wall contact angle. It has been found that it is a linear relationship between the droplet size and membranes pore size. At high porosities, it is more likely for droplets to coalesce at the membrane surface before they detach. If the porosity is too low, the dispersed phase flux may be not sufficient for viable production of emulsions. The thinner the membrane, the larger the flux through the pores will be, which leads to a higher droplet expansion rate. It has been observed that hydrophilic membranes are fit for making O/W emulsions and hydrophobic membranes for W/O emulsions. The droplet size decreases sharply as the cross-flow velocity increases from rest and reaches a size where it becomes more or less independent of the flow velocity. The permeating flux is increased by increasing the transmembrane pressure. Another important parameter affecting the droplet size is the wall contact angle. Higher wall contact angle results in larger droplets and a more poly-disperse emulsion.

Drinking Water Treatment

A. Moura Bernardes

Universidade Federal do Rio Grande do Sul (PPGE3M-UFRGS), RS, Porto Alegre, Brazil

Drinking water treatment includes the processes and operations applied in order to obtain an adequate and continuous supply of clear, colorless, odorless, palatable, and safe water.

The drinking water treatment requirements differ according to the feed water quality. Many aquifers and isolated surface waters are high in water quality and may be pumped from the supply and transmission network directly to any number of end uses, including human consumption. Source protection, i.e., conservation and protection of catchment areas, although not strictly in the category of treatment, can play a critical role in supporting the quality of water supplies (Sullivan et al. 2005). However, clean water sources are the exception in many parts of the world, particularly regions where the population is dense or where there is heavy agricultural use. In these places, the water supply must receive varying degrees of treatment before distribution (Peirce et al. 1998).

The most common water treatment process, known as conventional treatment, consists of coagulation, flocculation, sedimentation, filtration, and disinfection. Taken together, coagulation, flocculation, sedimentation, and filtration effectively remove many contaminants. Equally important, they reduce turbidity, yielding water of good clarity and hence enhanced disinfection efficiency. If not removed by such methods, particles may harbor microorganisms and make final disinfection more difficult. Generally, disinfection is

accomplished through the addition of an oxidant. Chlorine is by far the most common disinfectant used to treat drinking water, but other oxidants, such as chloramines, chlorine dioxide, and ozone, are also used. Although ultraviolet (UV) light can be used, it does not leave a residual, and usually a secondary disinfectant (i.e., chlorine) is added (Pepper et al. 2008).

In many cases, an additional treatment is necessary to remove suspended, colloidal, and dissolved constituents remaining after conventional treatment. Dissolved constituents may range from relatively simple inorganic ions, such as calcium, potassium, sulfate, nitrate, and phosphate, to an ever-increasing number of highly complex synthetic organic compounds (Tchobanoglous et al. 2003).

The ability of a water treatment facility to deliver a wholesome and high-quality product to its consumers usually occurs when advanced treatment methods are used. Activated carbon or granulated activated carbon (GAC) has been used to remove organic chemicals from water since the early 1900s. Ion exchange resins have been employed to remove inorganic metals for decades. Ozonation has been successfully used, instead of chlorine and bromine, to both disinfect water and oxidize organic constituents. Advanced oxidation processes have been used to remove persistent compounds. Ultraviolet light is being evaluated at a number of municipal treatment facilities for bacterial and viral control. Membrane separation processes are nowadays increasingly applied. As far back as 1985, the French have made use of membrane separation technology (i.e., reverse osmosis) for the removal of organic and inorganic compounds. Today, a number of reverse osmosis installations are operating worldwide to drinking water treatment. Reverse osmosis membranes can hold back a wide range of micropollutants including pesticides and pathogenic organisms and can replace the need for both ozonation and activated carbon filtration (Sullivan et al. 2005).

To produce fresh water from seawater and brackish water, desalination plants in industrial scale are nowadays installed throughout the world. Approximately one-half of the reverse osmosis (RO) systems currently installed are

used for desalinating brackish water or seawater (Baker 2012). Competing with RO, electrodialysis (ED) also plays an important role on the treatment of water in a very large market, a competition that is continuously intensified by the increased shortage of water resources. Both methods have advantages and disadvantages in drinking water treatment installations, and they have to be considered in order to choose the most optimal concept of membrane desalination.

Membrane fouling is one of the most important factors that limit greater use of desalination membranes. Fouling occurs due to particulate matter, organic matter, microorganisms forming biofilms, and inorganic scaling (Escobar 2010). Bacterial contamination problems have been reported as one of the main causes of membrane fouling in osmosis. This is caused by the characteristic of the membrane that serves as a barrier between the feed water and the product, which not only removes dissolved solids, but also bacteria, viruses, and insoluble substances. ED only removes ions. Therefore, any bacteria, colloidal material, or silica present in the feed water stream will remain in the product stream. This fact represents an advantage in terms of membrane fouling. On the other side, it can be seen as a major disadvantage, especially for the production of potable water, since microorganisms or organic contaminants are not eliminated.

By using ED technology, fouling can be minimized, thus decreasing the need for the addition of chemical products, by reversing the polarity of the system with electrodialysis reversal (EDR). By reversing the polarity (and the solution's flow direction) several times per hour, ions move in the opposite direction through the membranes, minimizing buildup. This generally minimizes membrane fouling, decreasing pretreatment requirements in comparison to RO (Seidel et al. 2011).

In general, electrodialysis reversal (EDR) is more attractive for the desalination of brackish water and in cases where the removal of organic matter and microbial control are not important. EDR is also of interest in treating brackish waters where silica is an important limitation (Escobar 2010). Nevertheless, the operating costs of

electrodialysis scale almost linearly in proportion to the salt concentration in the feed. Therefore, this technology is best suited to low-salt-concentration feed streams. Reverse osmosis costs also increase significantly with salt concentration but at a lower rate than electrodialysis does. The result is that reverse osmosis is the lowest-cost process for streams containing between 3,000 and 10,000 ppm salt. However, site-specific factors or plant size often make the technology the best approach for more dilute feed water or for streams as concentrated as seawater (35,000 ppm salt) (Baker 2012).

The salinity of brackish water is usually between 2,000 and 10,000 mg/L. The World Health Organization (WHO) recommendation for potable water is 500 mg/L, so up to 90 % of the salt must be removed from these feeds. Early RO cellulose acetate membranes could achieve this removal easily, so treatment of brackish water was one of the first successful applications of reverse osmosis. Several plants were installed as early as the 1960s. The osmotic pressure of brackish water is approximately 11 psi per 1,000 ppm salt, so osmotic pressure effects do not generally limit water recovery significantly. Limitations are generally due to scaling. Typical water recoveries are in the 70–90 % range, which means the brine stream leaving the system is up to ten times more concentrated in calcium, sulfate, and silica ions present in the feed. Disposal of the 10–15 % of the brackish water that remains as concentrated brine represents a significant problem. In fact, nowadays, brackish water desalination is the largest application of electrodialysis. The competitive technologies are ion exchange for very dilute saline solutions, below 500 ppm, and reverse osmosis for concentrations above 2,000 ppm. In the 500–2,000 ppm range, electrodialysis is often the low-cost process (Baker 2012). An advantage of electrodialysis compared to reverse osmosis is that a much higher brine concentration can be achieved, since there are no osmotic pressure limitations (Strathmann 2010). Typically 80–95 % of the brackish feed is recovered as product water. The degree of water recovery is limited by precipitation of insoluble salts in the brine (Baker 2012).

Seawater has a salt concentration of 3.2–4.0 %, depending on the region of the world. Because of this high salinity, only RO membranes with salt rejections of 99.3 % or more can produce potable water containing less than 500 ppm dissolved salt in a single pass. Application to seawater desalination of the first-generation cellulose acetate membranes, with rejections of 97–99 %, was limited. With the development of the polyamide hollow fine fibers and interfacial composites, suitable seawater membranes became available, and many plants have been installed. These membranes can produce permeate water that meets the WHO standard (<500 ppm salt) in a single pass or less than 200 ppm in a two-pass system, typically a single-stage seawater system and a single-stage brackish water system connected in series (Baker 2012).

Recently, membrane separation processes are being studied for the removal of emergent contaminants (e.g., pharmaceuticals and personal care products) from water. Surface and groundwater are the major renewable resources for sustainable drinking water production throughout the world. However, many chemical constituents that have not been considered historically as contaminants are present not only in wastewater, but also in natural waters at global scale. These emerging contaminants (EC) are commonly derived from municipal, agricultural, and industrial wastewater sources and pathways due to often inadequate treatment in conventional wastewater treatment plants, being detected in rivers downstream. In fact, the presence of EC can be expected in rivers, lakes, wells, and even drinking water. Considering that conventional water treatment with coagulation, sedimentation, and filtration achieves low levels of removal for EC, techniques that have been gaining attention in the past few years are pressure-driven membrane processes nanofiltration (NF) and reverse osmosis (RO). These two treatments seem to be able to effectively remove most organic and inorganic compounds and microorganisms from raw water, and their application in drinking water treatment has been seen as preferred alternatives for the removal of emerging organic contaminants (Quintanilla 2010; Radjenović et al. 2008).

Droplet Size

Emma Piacentini
Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Droplet size is defined by the diameter of an equivalent sphere having the same property (such as volume or mass) as the analyzed droplet. In order to simplify the interpretation of particle size distribution data, a range of statistical parameters can be opportunely selected for any given sample. The most common droplet size in a droplet size distribution could be reported as:

- Mean: average size of a population
- Median: size where 50 % of the population is below/above
- Mode: size with highest frequency

There are many different means that can be defined depending upon how the droplet size distribution is analyzed. The three most commonly used for particle sizing are:

- Surface area mean $D[3, 2]$ (Sauter mean diameter)

It is the weighted average surface diameter, assuming spherical particles of the same surface area as the actual particles:

$$D[3, 2] = \frac{\sum D_i^3 n_i}{\sum D_i^2 n_i}$$

It is most relevant where specific surface area is important, e.g., bioavailability, reactivity, and dissolution. It is most sensitive to the presence of fine droplets in the size distribution.

- Volume moment mean $D[4, 3]$ (De Brouckere mean diameter)

It is the weighted average volume diameter, assuming spherical particles of the same volume as the actual particles:

$$D[4, 3] = \frac{\sum D_i^4 n_i}{\sum D_i^3 n_i}$$

It is relevant for many samples as it reflects the size of those particles which constitute the bulk of the sample volume. It is most sensitive to the presence of large particulates in the size distribution.

- Number length mean $D[1, 0]$

It is often referred to as the arithmetic mean:

$$D[1, 0] = \frac{\sum D_i n_i}{\sum n_i}$$

It is most important where the number of particles is of interest, e.g., in particle counting

applications. It can only be calculated if we know the total number of particles in the sample and is therefore limited to particle counting applications.

For volume-weighted particle size distributions, such as those measured by laser diffraction, diameter is reported based upon the maximum particle size for a given percentage volume of the sample. The most common diameters are the Dv10, Dv50, and Dv90 that are corresponded to 10, 50, and 90 vol% on a relative cumulative droplet size curve, respectively.

Drug Delivery by Membrane Operations

Catherine Charcosset

Université Lyon 1, Lyon, Villeurbanne, France

Drug delivery is a field of vital importance to medicine and healthcare. A drug delivery system is a formulation or a device that enables the introduction of a therapeutic substance in the body and improves its efficacy and safety by controlling the rate, time, and place of its release (Jain 2008). It includes the administration of the therapeutic product, the release of the active ingredients by the product, and the subsequent transport of the active ingredients across the biological membranes to the site of action. A drug delivery system may be (1) a device used to deliver the drug or (2) a formulation of the drug which will be administered for a therapeutic purpose. Drugs may be introduced into the human

body by various anatomical routes. The choice of the route of administration depends on the disease, the effect desired, and the product available. Drugs may be administered directly to the organ affected by the disease or given systemically and targeted to the organ. Methods of systemic drug delivery are classified as follows: gastrointestinal system (oral, rectal), parenteral, transnasal, pulmonary (drug delivery by inhalation), transdermal, and intraosseous infusion. The oral route of drug administration is the most used for both conventional as well as novel drug delivery. The reasons for this preference are the ease of administration and widespread acceptance by patients.

Membrane devices used to deliver the drug consist basically of a drug reservoir (Stamatialis et al. 2008). Two main types of systems can be distinguished: (1) osmotic membrane systems and (2) diffusion-controlled membrane systems. An osmotic system consists of a reservoir made of a polymeric membrane permeable to water but not to the drug (semipermeable membrane) Fig. 1. The reservoir contains a concentrated drug solution. As water crosses the membrane due to osmotic pressure, the drug solution is released through the orifice. In diffusion-controlled membrane systems, the drug release is controlled by transport of the drug across a membrane. The transport is dependent on the drug diffusivity through the membrane and the thickness of the membrane. These systems find broad application in pills, implants, and patches (see Drug-Delivery Applications).

Membrane-based formulations used to deliver the drug consist of carriers that are biodegradable, biocompatible, targeting, and stimulus responsive

Drug Delivery by Membrane Operations,
Fig. 1 Schematic view of an osmotic drug delivery system

like liposomes and nanocapsules (Zhang et al. 2013). Liposomes are enclosed spherical vesicles that are organized in one or several concentric phospholipid membrane bilayers with an aqueous phase inside. Liposomes can entrap hydrophilic pharmaceutical agents in their internal aqueous compartment and lipophilic drugs within the lipid membrane. Nanoparticles (nanospheres and nanocapsules) are ranging in size from about 10 to 1000 nm. Nanospheres have a matrix type structure with drugs adsorbed at their surface, entrapped in the particle, or dissolved in it. Nanocapsules have a polymeric shell membrane and an inner liquid core, the drugs being dissolved in the inner core or adsorbed at their surface. Nanoparticles have been investigated for the entrapment of a wide variety of drugs, for applications ranging from ophthalmic delivery to carriers in chemotherapy.

Drug Delivery, Application of

Catherine Charcosset

Université Lyon 1, Lyon, Villeurbanne, France

Drug delivery membrane systems include osmotic membrane systems, diffusion-controlled membrane systems (pills, implants, patches), and

transdermal drug delivery (passive diffusion, iontophoresis, and skin or device-controlled delivery) (Grassi 2009). These drug delivery applications concern mainly transdermal, oral, and ocular delivery routes of administration.

In transdermal drug delivery (Stamatialis et al. 2008), the drug is incorporated into a patch and delivered through the skin due to the concentration difference or electrical current (Fig. 1). Transdermal patches are used as a convenient and effective method of drug delivery through the human skin. A membrane may exclusively control or partially control drug transport together with other components (such as the adhesive layer). Patches are commercialized, for example, for delivery of nicotine for smoking cessation, estrogen or testosterone for hormonal therapy, and methylphenidate for attention-deficit/hyperactivity disorder. Ocular patches are membrane-controlled reservoir systems. The drug, accompanied by carriers, is captured in a thin layer between two transparent, polymer membranes, which control the rate of drug release. The device is placed on the eye where it floats on the tear film. The drug slowly diffuses to the target area.

As a noninvasive transdermal drug delivery method, iontophoresis applies electrical current to deliver drugs through the skin to the underlying tissue or capillaries and then to the whole circulating system (Fan et al. 2008). A voltage applied between two electrodes immersed in a drug solution causes the drug to be moved from the donor part into the skin. The positively charged electrode (anode) attracts the negatively charged drug ions; the negatively charged electrode (cathode) attracts the positively charged ions. These devices are commercialized for example for delivery of lidocaine and epinephrine in local analgesia.

In oral delivery, the drug is pressed into a tablet which is coated with a nondigestible hydrophilic membrane such as cellulose esters like cellulose acetate, cellulose acetate butyrate, cellulose triacetate, and ethyl cellulose (Stamatialis et al. 2008; Grassi 2009). Once the membrane gets hydrated, a viscous gel barrier is formed, through which the drug slowly diffuses. The release rate of the drug

Drug Delivery, Application of,

Fig. 1 Schematic view of transdermal membrane delivery systems

is determined by the type of membrane used. The key feature of these systems is that drug release is independent of pH and hydrodynamics of the external dissolution medium. The result is a robust dosage form for which the *in vivo* rate of drug release is comparable to the *in vitro* rate, producing an excellent *in vitro/in vivo* correlation. Another key advantage is that they are applicable to drugs with a broad range of aqueous solubility such as diltiazem HCl, carbamazepine, metoprolol, oxprenolol, nifedipine, and glipizide.

Another example is implants which consist of a membrane reservoir containing a drug in liquid or powder form (Grassi 2009). The drug slowly diffuses through the nondegradable membrane that usually consists of silicone and ethylene-co-vinyl acetate. By properly choosing membrane thickness and permeability, release kinetics can be controlled and designed for a specific therapeutic target. For example, an implantable 5-year contraceptive permits the long-term release of levonorgestrel.

Drug Permeability

Catherine Charcosset

Université Lyon 1, Lyon, Villeurbanne, France

An important property of a drug is its bioavailability. For an orally administered drug, the bioavailability is mainly limited by its solubility and permeability through the intestinal epithelia. It is therefore important to have access to drug permeability. Today the most often used methods are the Caco-2 model and the parallel artificial membrane permeation assay (PAMPA).

Caco-2 cells are human colon epithelial cancer cell lines used as a model of human intestinal permeation of drugs and other compounds (van Breemen and Li 2005). When cultured as a monolayer, Caco-2 cells differentiate to form tight junctions between cells to serve as a model of paracellular movement of compounds across the monolayer. Caco-2 cell monolayers are usually cultured on semipermeable plastic supports that may be fitted into the wells of multi-well culture plates. Test compounds are then added to either sides of the monolayer. After incubation, aliquots of the solution in opposite chambers are removed for the determination of the concentration of test compounds. The apparent permeability coefficients are then calculated. Radiolabeled compounds used in the original Caco-2 cells monolayer assays have been replaced by the use of liquid chromatography mass spectrometry

(LC-MS) and LC-tandem mass spectrometry (LC-MS-MS). MS eliminates the need for radiolabeled compounds and permits the simultaneous measurement of multiple compounds.

The parallel artificial membrane permeability assay (PAMPA) is a possible low-cost alternative to cellular models (Avdeef 2005). Its popularity in the industry has risen rapidly. On the contrary to cell-based permeation assays, PAMPA assay contains artificial membrane that is used for evaluating the permeation properties of the compound. The system consists of phospholipid layer on a filter plate, half of which is treated with an organic solvent, mimicking the cell membrane. Various models with different lipids and/or organic solvent (hexadecane/dodecane) are used. Due to its artificial nature, PAMPA model predicts only passive permeation. When used in parallel with cell-based in vitro permeation assays (Caco-2), the differences in the results can reveal other than passive permeation mechanisms. PAMPA is suitable for high-throughput evaluation of passive permeation characteristics at multi-well culture plates, classifying compounds to high or low permeation. PAMPA assay can also be conducted at several physiologically relevant pH conditions (2–8), to see the effect of ionization of the compound to its passive permeation.

Another recent alternative to access to drug permeability properties is the phospholipid vesicle-based permeation assay (PVPA) developed for measurement of passive drug permeability (Fischer et al. 2011). The system consists of a tight layer of liposomes on a filter support which is obtained by first depositing smaller liposomes that will go into the pores and then larger liposomes that will layer on top of the filter, by use of centrifugation. Freeze-thaw cycling is then used to promote liposome fusion to generate a tight barrier used for permeability measurement. The characterization of the barrier structure showed that the pores of the filter are filled with liposomes and that there is a layer of liposomes on top of the filter.

Drug Release

Catherine Charcosset

Université Lyon 1, Lyon, Villeurbanne, France

Polymeric systems are often used to provide controlled release and protect the drug from biological degradation prior to its release. The development of these devices started with the use of nonbiodegradable polymers, which rely on the diffusion process, and subsequently progressed to the use of biodegradable polymers, in which swelling and erosion take place. Based on the physical or chemical characteristics of polymer, drug release mechanism from a polymer matrix can be related to three main mechanisms (Arifin et al. 2006):

- Drug diffusion from the non-degraded polymer (diffusion-controlled system).
- Enhanced drug diffusion due to polymer swelling (swelling-controlled system).
- Drug release due to polymer degradation and erosion (erosion-controlled system). Diffusion is involved in the three systems. For a nonbiodegradable polymer matrix, drug release is due to the concentration gradient by either diffusion or matrix swelling (enhanced diffusion). For biodegradable polymer matrix, release is controlled by the hydrolytic cleavage of polymer chains that lead to matrix erosion, even though diffusion may be still dominant when the erosion is slow.

Empirical and semiempirical mathematical models are often used to describe drug release from matrix-based drug delivery systems

(Siepmann and Peppas 2012). The most popular mathematical equation to describe the release rate of drugs from matrix systems is the Higuchi's equation (Higuchi 1961). Initially valid only for planar systems, it was later modified and extended to consider different geometries and matrix characteristics including porous structures. The equation of the Higuchi model is given as:

$$\frac{M_t}{A} = \sqrt{D(2c_0 - c_s)c_s t} \text{ for } c_0 > c_s \quad (1)$$

where M_t is the cumulative absolute amount of drug released at time t , A is the surface area of the controlled release device exposed to the release medium, D is the drug diffusivity in the polymer carrier, and c_0 and c_s are the initial drug concentration and the solubility of the drug in the polymer, respectively. Equation 1 can be expressed as:

$$\frac{M_t}{M_\infty} = K\sqrt{t} \quad (2)$$

where M_∞ is the absolute cumulative amount of drug released at infinite time (which should be equal to the absolute amount of drug incorporated within the system at time $t = 0$) and K is a constant reflecting the design variables of the system. Thus, the fraction of drug released is proportional to the square root of time. Alternatively, the drug release is proportional to the reciprocal of the square root of time.

Another commonly used semiempirical equation to describe drug release from polymeric systems is the power law:

$$\frac{M_t}{M_\infty} = 4\left(\frac{Dt}{\delta^2}\right)^{1/2} \left(\pi^{-1/2} + 2 \sum_{n=1}^{\infty} (-1)^n \operatorname{erfc} \frac{n\delta}{2\sqrt{Dt}} \right) \quad (3)$$

where M_t and M_∞ are the absolute cumulative amount of drug released at time t and infinite time, respectively; k is a constant incorporating structural and geometric characteristics of the device; and n is the release exponent, indicative of the mechanism of drug release. The classical Higuchi equation (Eq. 1) represents the special

case of the power law where $n = 0.5$. The power law describes in many cases dynamic swelling and drug release from glassy polymers.

Dry Spinning

Khayet Mohamed

Department of Applied Physics, Universidad Complutense de Madrid, Madrid, Spain

Dry spinning is an extrusion technique used for fabrication of fibers (filaments) or hollow fibers using a viscous dope solution containing polymer (s) dissolved in a volatile solvent or in a solvent mixture with a high volatility. The dope solution is pumped (extruded) through a filter and then through a spinneret or tiny orifices (i.e., jets) in a heated drying chamber. As the dope solution exit the spinneret, air or an inert gas is used to evaporate the solvent(s) so that the fiber solidifies and collected on a take-up wheel. Spinning is followed by stretching of the as-spun fibers to orient the polymer chains along the gas gap (fiber axis). In dry spinning the as-spun fibers do not come in contact with any precipitating liquid (bore liquid, external coagulant). Dry spinning differs from dry/wet spinning and wet spinning in that the solidification is achieved through evaporation of the solvent carried out by a stream of air or an inert gas. In dry spinning and melt spinning, the dimensions of the spinneret are not so crucial because the fiber dimensions are mainly determined by the ratio of the extrusion rate and

Dry Spinning,

Fig. 1 Schematic presentation of die swell occurring in the nascent fiber (a) and hollow fiber (b) when extruded from a spinneret

“tearing rate” (Mulder 1992). The gas flow used for solvent evaporation and solidification of the fibers influences to a significant extent the quality of the produced fibers. In dry/wet spinning and wet spinning, precipitating liquids are involved (bore liquid, external coagulant). In dry spinning, the fiber does not need to be dried like in wet spinning and dry/wet spinning. Examples of polymer used for production of fibers by dry spinning are cellulose acetate, polyacrylonitrile, polyurethane, and fibers based on poly-m-phenylene isophthalamide, polybenzimidazoles, polyamidoimides, and polyimides. In general, dry spinning is used for polymers that cannot be used in melt spinning. The concentration of the spinning dope solution and the spinning speeds is higher than those used in dry/wet spinning and wet spinning. Spinning speeds range between

300 and 1000 m/min. The spinning rate in melt spinning (thousands of meters per minute) is much higher than that used in the dry/wet spin technique (meters per minute) (Mulder 1992).

When a polymer solution is extruded through a tube in orifice spinneret, shear stress is induced within the spinneret (Fig. 1) (Khayet and Matsuura 2011). There are at least three forces (stresses) applied upon the dope solution: (i) shear and elongation stresses within the spinneret, (ii) gravity induced by the weight of the spun hollow fiber, and (iii) stress induced by the take-up system (i.e., wind-up drum or take-up wheel). It is known that the stress affects dramatically the polymer molecular orientation and relaxation at the outer surface of the nascent fiber. The effects of elongation and relaxation after exiting from the spinneret will play

important roles on final hollow fiber structure. Furthermore, the induced elongation stresses outside the spinneret from gravity through the air gap complicate the kinetics and dynamics of the phase inversion process. In addition, non-Newtonian polymer solutions may exhibit die swell and relaxation after exiting from spinneret.

Molecular chains tend to align themselves much better, and this enhanced orientation causes the polymer molecules to pack closer to each other leading to a tighter skin fiber structure. The molecular orientation induced by shear stress within the spinneret might relax in the air gap region, before reaching the take-up wheel, if the elongation stress along the spin line is small as spinning dope solution is a viscoelastic fluid or might be enhanced if the spin line stress is high. In other words, the elongation stress caused by gravity along the spinning line becomes more pronounced with increasing the distance between the spinneret or jets and the take-up wheel.

DSP&DE Model Applications

Patrick Fievet
Institut UTINAM, University of Franche-Comté,
Besançon, France

DSP&DE Model Applications

The applications of the Donnan/steric pore (DSP) and dielectric exclusion (DE) model (known as the SEDE model in literature) can be summarized as follows:

- (i) To characterize a *nanofiltration* (NF) membrane in terms of the average pore radius (r_p); the effective membrane thickness (δ); the

volume charge density (X), which is defined as the number of moles of fixed charges per unit of pore volume; the dielectric constant of the solution inside pores (ϵ_p); and the dielectric constant of the membrane material (ϵ_m)

Characterization using uncharged solutes:

r_p and δ are usually determined by the analysis of rejection data of neutral solutes (Bowen et al. 1997; Schaep et al. 1999; Labbez et al. 2002) since in that case the rejection only depends on structural parameters. Estimation of r_p and δ with various uncharged solutes shows that the variation in r_p for best fit is relatively small. Hence, a mean value of r_p can be considered. However, it is reported that the parameter δ varies significantly with solute size (Bowen et al. 1997; Schaep et al. 1999; Labbez et al. 2002). For an unknown solute, δ can then be obtained from a correlation between δ and r_i/r_p , r_i being the solute radius (Bowen et al. 1997). It was also found that the values of δ obtained from the fitting of the rejection data are different from that determined from water permeability measurements by using the Hagen-Poiseuille equation (Bowen et al. 1997; Labbez et al. 2002). As the quality of fitting obtained with an independent fit of both r_p and δ is much less good than that obtained using δ from permeability data, some authors recommend that the value of δ is not estimated from the permeability data for NF membranes.

Characterization using single-salt solutions:

The description of experimental rejection rates is in general satisfactory, and the fitted values of X appear to be physically reasonable when calculations are performed by neglecting DE mechanisms, i.e., by using the DSP model (based on a Donnan/steric exclusion mechanism). The analysis of rejection data shows that X is not constant but depends very much on the salt nature and its concentration. The increase in the

volume charge density with the salt concentration is probably caused by interactions between free ions in solutions and the membrane, where each individual ion contributes to the membrane charge by means of adsorption. However, the DSP model fails to describe the high rejection rates observed with some NF membranes in the case of solutions containing divalent counterions (Vezzani and Bandini 2002; Szymczyk and Fievet 2005). Indeed, the use of the DSP model leads to the prediction of unrealistic high volume charges or to a change of the sign of the membrane charge (which is not supported by streaming potential measurements) (Szymczyk and Fievet 2005) or to a ratio of the volume charge density to the salt concentration increasing with concentration (which disagrees with common adsorption isotherms) (Bowen and Welfoot 2002) or to the increase of the rejection rate as the membrane charge density X decreases (which is the opposite behavior from the one predicted by the *Donnan*/steric exclusion mechanism). This suggests that additional phenomena have to be accounted for so as to provide a better understanding, characterization, and prediction of NF membrane performances. However, it should be mentioned that the DSP model was proved to provide a coherent description of NF behavior for membranes at the borderline between UF and NF (membranes with larger pores and very thick active layers) as has been shown, e.g., in Lefebvre (2003) and Lefebvre et al. (2004) for ion rejection and filtration potential (i.e., the pressure-induced potential arising across membranes containing selective layers).

The DSP&DE model was shown to provide a rather good description of the rejection properties of both symmetric (KCl) and asymmetric (MgCl_2 , CuCl_2 , ZnCl_2 , NiCl_2 , CaCl_2) single-salt solutions by negatively charged organic membranes (AFC 30 and AFC 40 PCI NF

membranes) (Szymczyk and Fievet 2005; Szymczyk et al. 2007) with physically realistic values of ε_p (i.e., ranging from 42 to 69). However, literature shows that the approaches used to obtain a good agreement between theory and experiment differ depending on the couple membrane/salt studied. The description can be satisfactory considering (a) all exclusion mechanisms (Szymczyk and Fievet 2005; Szymczyk et al. 2006, 2007), or (b) steric, electric, and Born dielectric exclusion mechanisms (Cavaco Morão et al. 2008; Bouranene et al. 2009), or (c) steric, electric exclusion mechanisms and image forces (Bandini and Vezzani 2003; Bouranene et al. 2009).

Characterization using multi-ionic solutions:

In the case of 3-ion solutions, different approaches of the DSP&DE model have also to be used to appropriately describe the separation properties (Bouranene et al. 2009; Szymczyk et al. 2006). Unlike the results obtained with 2-ion and 3-ion solutions, the four exclusion mechanisms (*Donnan*, steric, Born, and image effects) are found to be unable to describe the experimental data in the case of solutions containing more ions. However, the description of the experimental rejection rates is quite satisfactory considering either Born dielectric effect or image forces (in addition to steric and electric exclusion mechanisms).

The application of the DSP&DE model was also extended to a complex solution of five ions (K^+ , Cl^- , NH_4^+ , SO_4^{2-} , and clavulanate ion), which mimics the industrial NF feed in the isolation process of clavulanate, which is a pharmaceutical product (Cavaco Morão et al. 2008). With a single-fitted parameter ε_p and considering that the ion selectivity is governed by *Donnan*, steric, and Born dielectric exclusion mechanisms, a good agreement was obtained between the

calculated rejections rates of the five ions and experimental values.

- (ii) To investigate the exclusion mechanisms in NF

The coupling between the various mechanisms involved in the ion rejection could be investigated. It was shown, e.g., that dielectric effects (i.e., Born dielectric effect and image forces) make the *Donnan* exclusion stronger. Indeed, unlike *Donnan* exclusion, image forces and Born dielectric effect do not differentiate (qualitatively) between coions and counterions since they are controlled by the square of the ion charge. As a result, both coions and counterions are excluded from pores by image forces. By decreasing the internal concentration, the dielectric exclusion phenomenon therefore reduces the screening of the membrane fixed charge and thus strengthens the electric exclusion. By contrast, the presence of a fixed charge on the pore walls as well as the ionic atmosphere surrounding an ion screens the interaction of this ion with the pore wall via image forces. The coupling between electric and dielectric exclusion mechanisms may result in a non-monotonous variation of the rejection with membrane charge density (X). It was also shown that the Born effect also strengthens the contribution of image forces.

The analysis of the rejection properties of a ternary ion mixture by an amphoteric ceramic membrane (Szymczyk et al. 2006) has shown that the dielectric constant inside the pores ϵ_p (which was fitted to experimental rejection rates) decreases with increasing normalized volume charge density (defined as the ratio of the membrane volume charge density to the total charge concentration in solution), which means that the presence of fixed charges at the pore walls (in addition to the confinement effect) could also have an influence on the orientation of solvent dipoles.

The DSP&DE model (more exactly the DSP model) was also applied to mixtures of uncharged solutes and ions in order to

investigate the significance of dehydration and pore swelling phenomena on the NF of neutral solutes, which could be responsible for the observed decrease in the neutral solute rejection in the presence of salts (Escoda et al. 2013). To this end, rejection properties of two NF ceramic and polymeric membranes were studied with single polyethylene glycol (PEG) solution and mixed PEG/inorganic electrolyte solutions. Rejection data obtained with the ceramic membrane (rigid pores) were used to compute the dehydration of the PEG molecules induced by the surrounding ions. Concerning the polymeric membrane, the decrease in the rejection rate was found to be systematically higher than for the ceramic membrane. The additional decrease was then ascribed to the swelling of the pores. The experimental data of rejection rates were then used to compute the variation in the mean pore radius in the presence of the various salts. For the two membranes, it was found that the contribution of the dehydration effect follows the Hofmeister series (Kunz 2004).

- (iii) To predict the rejection properties of a NF membrane

It must be stressed that accounting for the dielectric exclusion mechanism inevitably increases the number of fitting parameters, making the use of the DSP&DE model less appropriate for predictive purposes. Notably, the dielectric constant of the solution confined inside the membrane pores (ϵ_p) is used as a fitting parameter in all current versions of the DSP&DE model (Szymczyk and Fievet 2005, 2006, 2007; Escoda et al. 2011; Cavaco-Morao et al. 2008). Indeed, although in principle ϵ_p could be determined from dielectric relaxation measurements, in practice, the measurement of this parameter is extremely difficult due to (a) the multilayer (thick support layers) and composite (membrane material and confined solution) structure of NF membranes and (b) the pore size distribution. It must also be pointed out that the multilayer/composite structure and nanodimensional

pores make also the determination of the membrane charge density extremely difficult. Finally, unlike the DSP model, the prediction of membrane performances for multi-ionic systems by means of the adjustable parameters obtained for single-salt solutions is not possible with the DSP&DE model. Indeed, the choice for X and ϵ_p (ϵ_m being assumed to be known) allowing the description of experimental rejection rates is not unique for single-salt solutions because both electric exclusion and dielectric exclusion contribute to reject ions.

Dual Mode Sorption Model

Donald R. Paul

Department of Chemical Engineering, Texas Materials Institute, Austin, TX, USA

The **dual mode sorption model** is a convenient and commonly used equation for describing gas sorption in polymers at temperatures below the glass transition temperature, T_g , of the polymer. Gas sorption in glassy polymers generally (a) exhibits nonlinear isotherms that are concave to the pressure axis, unlike the linear ones seen above T_g , (b) shows greater levels than for rubbery polymers with the extent being larger the higher is the T_g , and (c) depends on the prior history of the sample and the details of the measurement protocol (Horn and Paul 2012). The first two aspects are well illustrated in Fig. 1 that shows the concentration of carbon dioxide, C , dissolved in five different polymers as a function

Dual Mode Sorption Model, Fig. 1 Sorption isotherms for CO₂ in various polymers at 35 °C (Reprinted with permission from Horn and Paul 2012. Copyright 2012 American Chemical Society)

of the pressure, p , in the external carbon dioxide gas phase. Butyl rubber shows a linear isotherm, while all four of the glassy polymers show features (a) and (b) mentioned above at this measurement temperature, i.e., $T = 35$ °C. The extent of carbon dioxide sorbed into these glassy materials increases the higher is the T_g ; i.e., their glass transition temperatures descend in the following order: 310 °C for the polyimide Matrimid 210 °C for poly(phenylene oxide) (PPO) 186 °C for polysulfone (PSF) 100 °C for polystyrene.

The dual mode sorption model consists of the sum of Henry's law term and a Langmuir term, i.e.,

$$C = k_D p + \frac{C'_H b p}{1 + b p} \quad (1)$$

where k_D is Henry's law coefficient, C'_H is the Langmuir capacity term, and b is an affinity parameter. It appears that Barrer et al. (1958) were the first to propose this now well-known equation. Equation 1 provides a very good fit of data like that in Fig. 1 where the C'_H obtained by the fitting would increase as the polymer T_g increases relative to the measurement

temperature T , i.e., $C'_H \sim T_g - T$, and is thought to be related to the unrelaxed volume of the glass; see Paul (2010) for a recent summary of the extensive literature in this area. The C'_H term would be zero for butyl rubber, i.e., Eq. 1 reduces to Henry's law, since it is not in the glassy state.

Petropoulos (1970) proposed that the Langmuir population may have a finite, but different, mobility than Henry's law population. Paul and Koros (1976) extended this analysis to give expressions for the time lag and the following expression for the permeability coefficient, P , for gases in glassy polymers:

$$P = k_D D_D + \frac{C'_H b D_H}{1 + b p_2} \quad (2)$$

where D_D is the diffusion coefficient associated with Henry's law population and D_H is the diffusion coefficient for the Langmuir population and p_2 is the upstream pressure of the permeating gas. This has become known as the **dual mobility model**. It predicts that the permeability decreases slightly as the upstream pressure increases and this is what is commonly observed experimentally in simple cases where the polymer is not plasticized significantly by the permeating gas.

Durability of Membrane (Lifetime of Membrane)

Colin A. Scholes

Department of Chemical and Biomolecular Engineering, University of Melbourne, Parkville, VIC, Australia

Durability (or lifetime) of membranes is a critical factor in the commercialization potential of any membrane material, as it must be resilient to the process conditions over an extended period of time. The lifetime of a membrane is also an important factor in the economic evaluation of a membrane process, as replacement of membranes is a significant cost burden.

A range of factors influence the durability of membrane materials. These include chemical degradation of either the active layer or support structure due to harsh chemical components in the feed stream, for example, feeds with low or high pH conditions, as well as high electrolyte concentrations, polymeric aging, and polymer plasticization, leading to increased probability of the active layer rupturing. An example of this is cellulose acetate membranes being plasticized by exposure to hydrocarbons in petrochemical gas separation applications; active layer compaction due to the extended exposure to high-pressure differentials across the membrane, resulting in reduced flux because of loss in diffusivity; and membrane fouling, which is the buildup of foreign matter on a membrane's surface resulting in decreased performance. An example is microbial growth in water treatment. Finally, mechanical abrasion of the active and support layers is caused by particulate matter being present in system. Each of these factors influences membrane materials differently, depending on the application.

There are a number of approaches to extend membrane lifetimes, most of which focused on overcoming membrane fouling. These include feed pretreatment, chemical and mechanical cleaning, feed stream pulsation, and pressure variation, as well as chemical additives to prevent

fouling in the first place. These techniques can extend a membrane module's lifetime but will not address issues such as chemical degradation, polymeric aging, and mechanical abrasion. Hence, all membrane modules' separation performances decrease over time in all industrial processes and replacement is necessary.

Currently, the industry standard is for a membrane module lifetime of ~5 years under standard process conditions (Li et al. 2008). For the majority of reverse osmosis membrane plants currently being commissioned or under construction, the RO membranes are guaranteed by the manufacturer for 5 years. Similarly, vapor separation membranes in the petrochemical industry have a lifetime of 3–5 years, dependent on the conditions of the feed. Seawater ultrafiltration membranes last up to 7 years because of their resilient material and the ability to avoid regular chemical cleans. Alternatively, dairy and brine processing membranes need to be replaced every year because of biological and particulate buildup, while hemodialysis and hemofiltration membranes are only required to function for a few hours, as they are single-use only equipment.

DuraMem™ Membrane

Ludmila Georgieva Peeva

Imperial College London, London, UK

DuraMem™ is a range of highly stable organic solvent nanofiltration (OSN) membranes manufactured by Evonik – Membrane Extraction Technology Ltd. (www.duramem.evonik.com). Membranes are of integral asymmetric type and are based on cross-linked polyimide (PI) (Great Britain 2007; Toh et al. 2007). These membranes

DuraMem™ Membrane, Fig. 1 A typical SEM micrograph of a cross section (*left*) and top separating layer (*right*) of cross-linked PI membranes (Adapted from Toh et al. (2007))

are available in formats of flat sheets and spiral-wound membrane modules within different molecular weight cutoff range ($150\text{--}900\text{ g mol}^{-1}$) and possess excellent stability in most of the organic solvents including polar aprotic solvents such as dimethylformamide (DMF) and *N*-methylpyrrolidone (NMP). The membranes have a spongelike structure (Fig. 1) and are usable in acetone, ethanol, methanol, tetrahydrofuran, dimethylformamide, dimethyl sulfoxide, dimethylacetamide, isopropanol, acetonitrile, methyl ethyl ketone, ethyl acetate, and others (www.duramem.evonik.com). The membranes have been operated continuously for 120 h in DMF and THF and showed stable fluxes and good separation performances, with DMF permeability in the range of $1\text{--}8 \times 10^{-5}\text{ Lm}^{-2}\text{h}^{-1}\text{Pa}^{-1}$ ($1\text{--}8\text{ Lm}^{-2}\text{h}^{-1}\text{bar}^{-1}$) (Toh et al. 2007). Possible re-imidization and loss of cross-linking at elevated temperatures limit their range of application to temperatures $<50\text{ }^{\circ}\text{C}$. The membranes can be operated in a pressure range of 20–60 bar (290–870 psi).

Dusty-Gas Model (DGM)

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

The Dusty-Gas Model is a transport model describing the motion of fluid mixtures through porous media. Its particular name is due to the main hypothesis behind its development: in a multicomponent system of n gas species moving within a porous medium, the porous medium itself is viewed as an additional $(n + 1)$ -th component of the mixture, consisting of giant molecules (or dust particles) constrained to remain fixed in the space by the presence of a virtual external force. However, if this virtual external force is removed, the model can be also used to describe motion of aerosols.

This model has been independently reinvented several times in the course of the history, starting with James Clerk Maxwell in 1860 (Maxwell 1980). However, it was only in 1983 that it was formalized as a mature theory by Mason and Malinauskas (1983), who described in detail the number of different hypotheses leading to corresponding different expressions of the model.

The Dusty-Gas Model is particularly important in *Membrane Technology*, as it can be used to describe the transport of a multicomponent fluid mixture through porous membranes and/or porous supports. Its use is not restricted to just ideal gases, but it can apply to real fluids as well, requiring the use of activities instead of partial pressures.

The model takes into account the following concurrent and independent transport modes:

- Knudsen flow (i.e., free-molecule flow), where the molecule-wall collisions are dominant over the molecule-molecule ones, so that the latter can be neglected.
- Continuum diffusion, where the species in mixture move with respect to each other by the effect of chemical potential gradient, which can include diffusion driven by concentration gradient, temperature gradient, and/or by external forces. In this case, the molecule-molecule collisions are dominant over the molecule-wall collisions.
- Viscous flow, where the mixture acts as a single fluid whose flow is promoted by the gradient of total pressure. In this case, the molecule-molecule collisions again dominate over the molecule-wall collisions.
- Surface diffusion is where the transport of the molecules over the surface in adsorbed state is dominant. This type of transport is usually negligible compared to the others, except for sufficiently small pore size, for which the adsorption forces are strong enough to constrain the molecule to mainly move over the surface. This kind of transport is usually precursors of phenomena like *multilayer adsorption* and *capillary condensation*.

The most important hypothesis that allows leading a usable mathematical form of the model is that all the involved transport modes act independently to each other. Under this hypothesis, the scheme behind the formalization of the Dusty-Gas Model can be represented by the following analog electric circuit (Fig. 1):

Dusty-Gas Model (DGM), Fig. 1 Analog electric circuit relative to the transport modes included in the Dusty-Gas Model

Neglecting surface diffusion and thermal diffusion, the mathematical form of the model can be expressed in the following manner:

$$\sum_{j=1}^n \frac{x_j \vec{N}_i - x_i \vec{N}_j}{C_T D_{ij}^{Bin} \frac{\varepsilon}{\tau}} + \frac{1}{D_i^{Kn} \frac{\varepsilon}{\tau}} \left[\frac{\vec{N}_i}{C_T} + \frac{x_i B_0 \frac{\varepsilon}{\tau}}{\eta} \left(\nabla P - C_T \sum_{j=1}^n x_j \vec{F}_j \right) \right] = -x_i \nabla \ln(x_i) - x_i \nabla \ln(P) + \frac{x_i \vec{F}_i}{RT} \quad (1)$$

where $\vec{N}_i$ [mol s⁻¹ m⁻²] is the total fluxes (i.e., diffusive + convective) of the *i*-th species, x_i its molar fraction, P [Pa] the total pressure, C_T [mol m⁻³] the total concentration, T [K] the temperature, D_{ij}^{Bin} [m² s⁻¹] is the binary diffusion coefficient relative to the generic species *i* and *j*, D_i^{Kn} [m² s⁻¹] is the Knudsen diffusivity, B_0 [m²] is a geometrical parameter depending on the structure geometry, η [Pa s] is the mixture viscosity, $\vec{F}_i$ is the resultant of all the possible external forces acting on the *i*-th species, and ε and τ are the medium porosity and tortuosity, respectively (all the vectorial entities are denoted with an arrow above).

Dynamic Free Volume

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical
Synthesis, Russian Academy of Sciences,
Moscow, Russia

Dynamic free volume appears in liquids (Frenkel 1946) and in polymers above their glass transition temperatures T_g , i.e., in *rubbers*. In liquids, it appears due to mobility of individual molecules, while in *rubbers* due to segmental mobility. Dynamic free volume influences such properties of the medium as diffusion and self-diffusion coefficients and viscosity. In glassy state, where the segmental mobility is frozen, still some local mobility of small side groups is possible as well as the corresponding *free volume*. When a glassy polymer is plasticized, that is, contains low molecular mass additives, their mobility can induce some mobility of the adjacent parts of the main or side chains. So the fraction of dynamic free volume in the total *free volume* can increase, the polymer becomes more “rubberlike,” and its properties (gas permeation parameters) become more similar to those of rubbers: increase in permeability and decrease in permselectivity. These phenomena are detrimental for separation of gas mixtures that contain great concentration of highly sorbed components like carbon dioxide (Sanders 1988). According to *molecular dynamics*, the average time of “settled” life of free volume elements in rubbers is very short – about several picoseconds (Hofmann et al. 2000). The mobility of any kinetic system is determined by the relaxation time τ : $\tau(T) = \tau_0 \exp(U/kT)$, where U is the activation energy and $\tau_0 = 10^{-12}$ s. It is often assumed that U increases at decreased temperatures and, hence, the relaxation times at the glass transition temperature $\tau(T_g)$ become longer than the intrinsic times of cooling of the high elastic system, i.e., vitrification occurs. These changes of U are caused by the decreases in the dynamic free volume in rubbers v_f . The dynamic (or fluctuation) free volume above T_g increases

with temperature according to the equation: $v_f = v_{fg}[1 + (\alpha_r - \alpha_g)(T - T_g)]$, where α_r and α_g are the coefficients of thermal expansion above and below T_g , respectively, and v_{fg} is the free volume at T_g . Originally, it has been assumed that the fraction of free volume at T_g , $f_c = v_{fg}/v$, where v is the specific volume of the polymer, is constant for most of the polymers and equal 0.025 ± 0.003 (iso-free volume concept of Simha-Boyer). Further studies showed that f_c varied in a much wider range and increases with T_g (Yampolskii et al. 2000).

The variation of the dynamic free volume in rubbers with temperature and as a function of T_g has important implications for membrane science: when the difference $T_{exp} - T_g$ increases (at constant T_{exp}), i.e., for the rubbers with lower T_g , e.g., polydimethylsiloxane, the transport parameters such as $P(T_{exp})$ and $D(T_{exp})$ strongly increase (van Amerongen 1964; Yampolskii et al. 1982). Here, T_{exp} is the ambient temperature at which the permeability and diffusion coefficients are usually measured. It means that the polymers with the lowest glass transition temperature have the greatest dynamic free volume at ambient temperatures.

The size of the elements of dynamic free volume in rubbers is relatively large: it should be compared with the size of kinetic segments, so much larger than the size of the typical gaseous penetrants. It means that the selectivity of diffusion in rubbers is very weak, and, because of this, in rubbers *solubility-controlled permeation* regime is realized.

Dynamic Mechanical Analysis

Chi Hoon Park

Gyeongnam National University of Science and Technology (GNTECH), Jinju-si, Gyeongsangnam-do, Republic Of Korea (South Korea)

Dynamic mechanical analysis (DMA) is a technique to study viscoelastic properties and modulus of elasticity of polymers by measuring the damping of an oscillatory signal of stress and strain. DMA results generally describe the variation of modulus values as a function of temperature or frequency (e.g., Fig. 1) and are widely used to detect the transitions such as glass transition temperature (T_g) or melting of polymer materials.

Figure 2a shows general schematic diagram of DMA apparatus; after a sinusoidal force is applied to the sample as an input signal, the resulting sinusoidal deflection or deformation is detected as an output signal, which contains information about the storage modulus E' , the dynamic loss modulus E'' , and the mechanical loss factor $\tan \delta$ (www.ngb.netzsch.com). According to the feature or types of sample materials, there are various modes of deformation as shown in Fig. 2b (www.ngb.netzsch.com), and this variety of sample holding method enables DMA to have wide

applications. For membrane samples, tension mode (fifth mode from the top in Fig. 2b) is generally adopted.

In the membrane applications, DMA is widely used for various fields such as fuel cell membranes, bio membranes, gas separation, pervaporation, etc. Page et al. applied DMA to investigate the structural characteristic of Nafion membranes well known as a fuel cell membrane (Page et al. 2005). In the study, two thermally reversible transitions of Nafion over room temperature were explained as glass transition by the short-range segmental motions within a static electrostatic network below 150 °C and the long-range chain/side-chain motion by thermally activated destabilization of the electrostatic network over 240 °C. Also, Xie reported that the perfluorosulfonic acid (PFSA) ionomer membrane showed a wide range of glass transition from ~55 °C to ~130 °C (Fig. 1), and based on the T_g result, he studied the multi-shape memory effect of PFSA (Xie 2010). Mano focused on the advantage of DMA that the test conditions can be more closely set to the physiological environments which the biomaterials will be applied to (Mano 2008). Using chitosan membranes, their mechanical properties were measured under low/moderate hydration conditions at different relative humidity (RH) levels and in completely wet (immersed) condition. Weng et al. synthesized intrinsically dopable polyimide (DPI) membranes containing an amine-capped

Dynamic Mechanical

Analysis, Fig. 1 Dynamic mechanical analysis (DMA) curve of perfluorosulfonic acid (PFSA) ionomer. $\tan \delta$ is the ratio between the loss modulus E'' and the storage modulus E' (Xie 2010) (Reprinted with permission from Macmillan Publishers Ltd: Nature 464:267–270, copyright (2010))

aniline trimer (ACAT) having high gas separation properties, where DMA results reported higher mechanical and thermal stabilities of the membranes than those of polyaniline (PANI) and conventional nondopable polyimide (NDPI) (Weng et al. 2011). Other examples are as follows: Budd et al. studied the mechanical stability of polymer of intrinsic microporosity (PIM-1) by DMA in the temperature range from 30 °C to 450 °C for pervaporation application (Budd et al. 2004); Nagarale et al. synthesized poly (vinyl alcohol)-SiO₂ hybrid membrane by

sol-gel method for a cation-exchange membrane, and its mechanical stability was measured by DMA (Nagarale et al. 2004); Gholap et al. synthesized hydrophobically modified PVA-g-polyNTBA membranes, where DMA was used to detect the crystallinity of the membranes as a function of annealing (Gholap et al. 2004); using DMA, Arjun and Ramesh studied the mechanical stability of the oxidatively stable polycarbonate urethane (PCU) membranes fabricated by electrospinning method for biomedical application (Arjun and Ramesh 2012); Ghassemi

Dynamic Membrane Emulsification

Emma Piacentini¹, Alessandra Imbrogno^{1,2} and Richard G. Holdich³

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²University of Calabria, Rende, Italy

³Department of Chemical Engineering, Loughborough University, Loughborough, Leicestershire, UK

Dynamic membrane emulsification (ME) refers to the formation of emulsion droplets by extruding the to-be-dispersed phase through the membrane

pores into the continuous phase, and the droplet detachment occurs by a surface shear. The regular droplet detachment from the pore openings is obtained by:

- (i) Moving the continuous phase in cross-flow, stirred, or pulsed mode
- (ii) Moving the membranes by rotation, vibration, or oscillation

In Table 1, techniques, shear stress profile, and forces acting on a forming droplet for each membrane emulsification process are illustrated.

In cross-flow mode, the shear stress is generated by the recirculation of the continuous phase tangentially to the membrane surface. This technique is called “*cross-flow ME*.” A typical cross-flow ME apparatus includes a tubular or flat-sheet microfiltration membrane, a pump for the recirculation of the continuous phase along the lumen side of the membrane, a feed vessel, and a pressured nitrogen gas container for the dispersed phase (Peng and Fellow 1998). Cross-flow ME is suitable for large-scale production and continuous or semicontinuous operation. However, droplet breakup can occur over time when concentrated emulsion is produced due to the high cross-flow velocities used to obtain narrow droplet size distribution at high dispersed phase flux or over long time of operation.

In pulsed-flow mode, a periodic flow pulsation is generated in the continuous phase without recirculation. This technique is called “*pulsed-flow ME*.” In a typical pulsed-flow ME apparatus, the dispersed and the continuous phases are injected using a pump, while the pulsed flow in the continuous phase is generated by a frequency generator (Holdich et al. 2013) or by inverting the flow direction back and forward within the membrane lumen (Piacentini et al. 2014). Pulsed-flow ME is advantageous for the production of emulsions with a high dispersed to continuous phase ratio, and it is suitable for large-scale production in continuous or semicontinuous mode.

In an alternative, the shear stress on the membrane surface can be generated by stirring the continuous phase. This technique is called “*stirred membrane emulsification*.” In a typical stirred ME

Vibrating ME 	Continuous Phase 	

device, the dispersed phase is injected through the membrane pores by using a pump or nitrogen gas while stirring the continuous phase with a rotator when a tube-shaped submerged membrane is used or with a paddle blade stirrer in the case of a flat-sheet membrane (Stillwell et al. 2007). Stirred ME is useful for emulsion production at batch scale, in the laboratory, and it is especially used to study the effect of different experimental conditions and chemistry on the formulation properties.

In *rotating ME*, the dispersed phase is introduced into the center of a rotating tubular porous membrane, and droplets are detached at the membrane wall in the radial direction into the stationary continuous phase (Vladisavljević and Williams 2006). The pressure is generated in the membrane lumen by using nitrogen gas or a pump, while the membrane is rotated in the continuous phase by an overhead stirrer. Rotating ME is particularly advantageous for the production of coarse emulsions and fragile structured products in which the droplets and/or particles are subject to breakage during the pump recirculation. However, the use for large-scale production is limited due to the complicated and more expensive design and higher power consumption compared to alternative designs.

The *vibrating ME* principle is similar to the rotating ME except for the use of oscillation of the membrane perpendicularly with respect to the dispersed phase injection direction (Holdich et al. 2010). The frequency and amplitude of the axial oscillation of the membrane was generated by an electrically driven vertical oscillator and could be controlled separately.

In *azimuthally oscillating ME*, a tubular membrane is periodically rotated back and forward in a slowly cross-flowing continuous phase, while the dispersed phase is radially injected in the lumen side of the membrane using a pump (Silva et al. 2015). The azimuthal (tangential) oscillation of the membrane is controlled by a control panel which is connected to the oscillator motor providing separate control over the frequency and membrane displacement. Azimuthally oscillating ME operates in a continuous mode, and it is suitable for large-scale production providing high

production rates, facilitating easy process automation and reduced operation time.

In dynamic ME, the forces acting on a droplet at the membrane pore level include detaching forces, driving droplets off the pore, and retaining forces, holding droplets on the pore. Detaching forces are drag (F_D), buoyancy (F_{BG}), inertial (F_I), lift (F_L), and static pressure (F_{SP}) force, while the main retaining force is the interfacial tension (F_γ). The drag force (F_D) is created either by moving the continuous phase parallel to the membrane surface or by moving the membrane; the buoyancy force (F_{BG}) is due to the density difference between the continuous phase and the dispersed phase; the inertial force (F_I) is caused by the dispersed phase flow moving out from the pore outlet; the dynamic lift force (F_L) results from the asymmetric velocity profile of the continuous phase near the droplet; static pressure (F_{SP}) force is due to the pressure difference between the dispersed phase and the continuous phase at the membrane surface; the interfacial tension force (F_γ) represents the effect of dispersed phase adhesion around the edge of the pore opening. In the case of “moving membrane” emulsification, additional (or enhanced) forces have to be considered.

For rotating membrane emulsification, compared to a nonrotating system, the drag force created by the membrane rotation (F_{DR}) has to be taken into account, and the gravitational body force is replaced by the centrifugal force (F_C) resulting from centrifugal acceleration and density difference of the two phases. High centrifugal force may be responsible for polydisperse emulsion production in the case of O/W emulsion due to deformation of the emerging oil drops and induced flow of oil drops toward the membrane surface causing coalescence and wetting of the membrane.

For an oscillating membrane system where the membrane is axially excited, an additional drag force (F_{DE}) and inertial force (F_{IE}) appear in the direction parallel to the membrane. This is due to a sudden change in the direction of the membrane which induces a velocity difference in the column of liquid inside the membrane and localized high pressure at the peak positions of the vertical oscillation (i.e., top and bottom of the membrane tube).

In *dynamic* ME, the droplet breakup process is correlated with a *dripping* or *jetting* behavior depending on the relative strength of the different forces acting on the process. In the dripping region, the inertial force is negligible compared to the drag force or unable to overcome the surface tension force. Thus, the droplet size is affected mainly by the drag force imparted by the continuous phase flow or moving membrane and the surface tension force. The inertial force of the dispersed phase has negligible effect in drop detachment in the dripping mode. It is shown that the droplet size becomes smaller as the shear stress increases and the influence is more significant for low shear values and smaller pore size. At high dispersed phase flow rates, the inertial force exceeds the surface tension force, leading to a transition to jetting behavior. In this case, the droplet detachment point moves further downstream from the pore usually resulting in the formation of a larger droplet than when in the dripping regime.

The different process conditions can be accurately tuned to control the shear stress in dynamic ME according to the mechanism used to generate the drag force (flowing of continuous phase or moving membrane); the following provides some simplified equations for shear at the membrane surface according to the method of generation of that shear:

- In cross-flow ME, the shear stress (τ) [Pa] is constant over the tubular membrane area, and it is correlated with the tangential velocity of the flowing continuous phase (v) [ms^{-1}], the density of the emulsion (ρ) [kgm^{-3}], and the friction factor (λ) which is calculated depending on the Reynolds number ($\lambda = 16/\text{Re}$ for $\text{Re} < 2000$; $\lambda = 0.0792 \text{ Re}^{-0.25}$ for $\text{Re} > 2000$) Eq. 1:

$$\tau = \frac{\lambda \rho v^2}{2} \quad (1)$$

- In stirred ME, the shear stress (τ) [Pa] depends on the angular velocity (ω) [s^{-1}] of the stirrer. The shear over the whole membrane area can be calculated with the Eqs. 2 and 3:

$$\tau_{\max} = 0.825 \mu_c \omega r_{\text{trans}} \frac{1}{\delta} \quad \text{for } r < r_{\text{trans}} \quad (2)$$

$$\tau = 0.825 \eta_c \omega r_{\text{trans}} \left(\frac{r_{\text{trans}}}{r} \right)^{0.6} \frac{1}{\delta} \quad \text{for } r < r_{\text{trans}} \quad (3)$$

where μ_c [Pa s] is the continuous phase viscosity, r_{trans} is the transitional radius, and δ is the boundary layer thickness given from the Landau-Lifshitz equation ($\delta = \sqrt{\mu/\omega\rho}$). The shear stress is not uniformly distributed over the membrane surface, and it can be assumed that the maximal shear ($\tau_{\max}$) is reached at distance r_{trans} from the center of the membrane; r_{trans} is the transitional radius in which the rotation changed from a free vortex to a forced vortex.

- In rotating ME, the shear stress is directly proportional to the membrane rotational speed (n) [rpm] but depends also on the width of the annular gap between the rotating membrane and the stationary vessel. The shear at the surface of the membrane is calculated using Eq. 4:

$$I? = \frac{I?R_1^2 n}{15(R_2^2 - R_1^2)} \quad (4)$$

where R_1 is the radius of the rotating membrane and R_2 is the radius of the stationary vessel.

- Pulsed ME and vibrating and azimuthally oscillating ME are based on the generation of the shear stress by oscillation of either the continuous phase or the membrane. Thus, there are two parameters affecting shear stress on the membrane surface: frequency (f) [Hz] and amplitude (a) [m] of the oscillation. During the oscillation, the shear is variable and the emerging drop detaches when it experiences the maximum shear stress which is calculated using Eq. 5:

$$\tau_{\max} = 2a(\pi f)^{3/2}(\mu\rho)^{1/2} \quad (5)$$

where μ is the viscosity and ρ is the density of the continuous phase. A peak shear event occurs twice per oscillation: once in each direction that the wave

is moving, for a regular wave form such as a sine wave.

Dynamic Membrane Microfiltration

Michel Jaffrin

Department of Biological Engineering,
Technological University of Compiegne, BP
20529, Compiegne Cedex, France

Introduction

To separate molecules or particles from a solution by cross-flow filtration through a membrane, it is necessary to circulate the fluid at a speed of $3\text{--}6\text{ ms}^{-1}$ in a tubular or plane membrane in

order to prevent the buildup of a layer of rejected solutes on the membrane while exerting a pressure on the fluid to produce a filtrate. The combination of high feed pressure and flow rate requires powerful and expensive pumps that consume energy and the friction creates a pressure decay along the membrane which reduces the transmembrane pressure (TMP). In addition, the rejected molecules or particles can create a cake on a microfiltration (MF) membrane which reduces both filtration rate and solute transmission through the membrane.

Dynamic filtration is a recent alternative to classical cross-flow filtration (Lee et al. 1995; Jaffrin 2008) consisting in creating a high shear rate (velocity gradient) at the membrane by a disk or a rotor rotating near the membrane or by using rotating or vibrating membranes, while using a low feed flow rate, only slightly larger than the permeate flow rate.

Advantages and Drawbacks of Dynamic Filtration

The first advantage is a substantial increase in permeate flux at all membranes cut-off due to shear rates which can reach $3\text{ }10^5\text{ s}^{-1}$ when using disks with radial vanes rotating at high speed. Due to moderate fluid velocities inside the module, the transmembrane pressure remains relatively uniform, which contributes to flux increase. Clarification of a suspension by MF requires a good solute transmission which is augmented by cake reduction. In ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) the permeate flux is mainly limited by the concentration polarization layer made of molecules rejected by the membrane. This layer is diminished by high shear rates which increases back transport of solutes away from the membrane. The flux keeps increasing with rising TMP until pressures of 40 bars at high shear rates. The combination of these two factors, high TMP and high shear rates, yields frequently permeate fluxes five times higher than in cross-flow filtration with the same membrane and same fluid. In addition, in NF and

Dynamic Membrane Microfiltration,

Fig. 1 Industrial VSEP vibrating modules (Courtesy of New Logic Research)

Dynamic Membrane Microfiltration,

Fig. 2 Dyno rotating disk module (Bokela, Germany)

RO applications, such as wastewater treatment, it is important to have a small microsolutes concentration in permeate. This is the case in dynamic filtration as the diffusive mass transfer through the membrane is greatly reduced by the small solute concentration at the membrane.

The main drawbacks are higher costs of equipment and maintenance due to moving parts and more complex design and membrane area limitations for some systems. The recent availability of 30 cm diameter ceramic membrane disks has permitted the development of systems with ceramic

disks rotating around several parallel shafts in a closed tank, with a total membrane area exceeding 120 m^2 which are cheaper to build and to service than multicompartiment modules with metal disks rotating between fixed organic membranes.

Rotating disks modules give a choice between using high rotation speeds to maximize the flux and thus minimize membrane area and investment cost, or to use moderate speeds to obtain the same flux as with tubular membranes but saving more than 60 % of the energy spent per m^3 of permeate with these membranes.

Industrial Filtration Modules

VSEP Vibrating Modules (New Logic Research, Ca, USA)

Close to 400 VSEP systems have been installed worldwide since their introduction around 1995.

They consist of a stack of circular organic membranes in separate compartments oscillating azimuthally around a vertical shaft at a resonant frequency of about 60 Hz. The maximum membrane area is 150 m² and the power spent in vibrations is only 9 kW (Fig 1). It can sustain

pressures of 40 bars and is used with a wide choice of membranes from MF to RO Al-Akoum et al. (2002).

Single Shaft Rotating Disks Systems

Bokela GmbH (Karlsruhe, Germany) commercializes the Dyno with metal disks rotating between fixed circular membranes of 12 m² for MF and UF (Fig. 2).

Metso Paper (Raisio, Finland) manufactures the Optifilter CR with blades rotating between fixed membranes of 1 m diameter and up to 140 m² membrane area with a 132 kW motor (Fig. 3).

Multishaft Rotating Ceramic Membrane systems

KMPT GmbH (Vierkirchen, Germany) commercializes a two-shaft module with 15 cm diameter overlapping ceramic membranes of 16.4 m² area (Table 1).

Conclusion

Dynamic filtration is not intended for initial treatment of huge volumes of fluids, but it should be well adapted to “end of pipe treatment” when the goal is to reach high solid concentration in retentate or to extract valuable components in highly charged suspensions.

Dynamic Optimization of Membrane Operation

Radoslav Paulen

Department of Biochemical and Chemical Engineering, Technische Universität Dortmund, Dortmund, Germany

Dynamic optimization is usually referred to open-loop optimal control. It encompasses several methods whose purpose is to determine trajectories of dynamic (time-dependent) variables in optimal manner. These methods may be used to find optimal control of processes or to design optimal experiments for parameter estimation. The generalized representation of dynamic optimization problem (DOP) is as follows

$$\min_{\mathbf{u}(t)} \mathcal{G}(\mathbf{x}(t_f), t_f) + \int_{t_0}^{t_f} \mathcal{F}(\mathbf{x}(t), \mathbf{u}(t), t) dt \quad (1)$$

$$\text{s.t. } \dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t), t) \quad (2)$$

$$\mathbf{h}(\mathbf{x}(t_0), t_0, \mathbf{x}(t_0), t_f) = 0 \quad (3)$$

$$\mathbf{g}(\mathbf{x}(t), \mathbf{u}(t), t) \leq 0 \quad (4)$$

where t is time, $\mathbf{u}(t)$ denotes vector of control variables, $\mathbf{x}(t)$ is vector of state variables, and $G(\cdot)$ and $F(\cdot)$ stand, respectively, for nonintegral and integral part of optimization objective. The set of differential Eq. (2) represents dynamical system. This is usually the model of the process whose optimal control one searches for. Sets of functions $\mathbf{h}(\cdot)$ and $\mathbf{g}(\cdot)$ may express various types of equality/inequality constraints which are imposed by the physical reality.

In order to find solution to DOP, one can exploit various techniques, stochastic (such as genetic algorithms, simulated annealing, etc.) or deterministic ones. Deterministic methods are based on the following three principles: variational calculus (developed by Euler and Lagrange), dynamic programming (Bellman 1957), and Pontryagin's maximum/minimum

principle (Pontryagin et al. 1962). The latest one gave rise to most popular numerical techniques such as control vector parameterization, control vector iteration, boundary condition iteration, orthogonal collocation, and multiple shooting techniques.

Various dynamic optimization problems were solved already in literature on membrane processes. These applications include optimization of membrane reactors performance (Parvasi et al. 2009; Rahimpour and Elekaei Behjati 2009), other membrane-assisted processes (Kuhn et al. 2009; Bui et al. 2010), membrane separation (Fikar et al. 2010; Paulen et al. 2011) as well as membrane fouling and cleaning (Van Boxtel and Otten 1993; Blankert et al. 2006; Zondervan and Roffel 2008).

Dynamic-Volume Diafiltration

Zoltán Kovács

Department of Food Engineering, Institute of Bioengineering and Process Engineering, Szent Istvan University, Budapest, Hungary

Dynamic-volume diafiltration is a type of batch diafiltration process that is designed to achieve the twin aims of simultaneous macrosolute concentration and microsolute removal by employing optimal time-varying control of diluant feeding.

The technological goal in a general batch process is to increase the macrosolute concentration from $c_{1,0}$ to $c_{1,f}$ and to reduce the microsolute concentration from $c_{2,0}$ to $c_{2,f}$. The fractionation is accomplished by introducing a diluant into the feed reservoir. Choosing the right strategy of scheduling the addition of diluant is a critical aspect to consider in batch processing (Lutz 1997). Processes can be characterized upon their α -strategies (α is the ratio of diluant flow rate to permeate flow rate). Frequently used batch diafiltration techniques, such as traditional diafiltration, variable-volume diafiltration, pre-concentration followed by variable-volume diafiltration, intermittent feed diafiltration, and sequential dilution diafiltration, employ arbitrarily predefined schemes of diluant addition. In contrast, dynamic-volume diafiltration is designed by the evaluation of the optimal time-

varying profile of diluant flow for the entire course of operation.

The process of dynamic-volume diafiltration poses a dynamic optimization problem (Fikar et al. 2010). The goal of optimization is to find the optimal time-dependent function of α that drives the process from its initial state to a prescribed terminal state. Optimality is defined as the minimization of the objective function J without violating given constraints. The mathematical problem can be formulated as follows:

$$\begin{aligned} \min_{\alpha(t)} \mathcal{J} \quad & \text{s.t.} \\ \dot{c}_1 &= \frac{c_1 q}{V} (R_1 - \alpha), \quad c_1(0) = c_{1,0}, \\ c_1(t_f) &= c_{1,f}, \quad \dot{c}_2 = \frac{c_2 q}{V} (R_2 - \alpha), \\ c_2(0) &= c_{2,0}, \quad c_2(t_f) = c_{2,f}, \\ \dot{V} &= (\alpha - 1)q, \quad V(0) = V_0, \\ \alpha &\in [0, \alpha_{\max}] \end{aligned}$$

where c_1 , c_2 , and V represent the actual macrosolute concentration, microsolite concentration, and volume in the feed tank, respectively. It is assumed that the system is well mixed and the diluant is solute-free. R_1 and R_2 denote the rejection of macrosolute and microsolite, respectively. It should be mentioned that, in a general case, the actual value of both q and R depends on the concentrations of macrosolute as well as on microsolite. Moreover, process parameters (e.g., pressure, temperature, hydrodynamic conditions, etc.) also affect q and R .

In practice, several objective functions can be considered for optimization, for instance, time minimization:

$$J_A = t_f$$

diluant minimization:

$$J_B = \int_0^{t_f} \alpha(t) q(t) dt$$

or minimization of complex economic index:

$$\begin{aligned} J_C = & k_1 t_f + k_2 \int_0^{t_f} c_1 [1 - \mathcal{R}_1(t)] q(t) dt \\ & + k_3 \int_0^{t_f} \alpha(t) q(t) dt \end{aligned}$$

where total cost is a sum of three terms that are the operational cost of the pump, cost of the valuable component loss, and the cost of the utilized dilution water. k_1 , k_2 , and k_3 , are the respective cost factors.

This technique can be useful to evaluate optimal operation of membrane filtration plants including reverse osmosis, ultrafiltration, nanofiltration, and microfiltration systems (Paulen et al. 2012). In general, optimal α control need not to be any of the conventional diafiltration concepts, and thus, it might need advanced control systems. In many cases, however, it might be attractive to implement the optimal trajectory since it can lead to reduced operation time, diluant consumption, and product losses. The computed optimal profile may vary case by case depending on the complexity of the membrane response model, the initial and final values, and the constraints involved in the model.

Ease of Expansion in Gas Separation

Adele Brunetti

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Quite often during the operation of a system for the treatment of gases, it is necessary to expand it for treating greater streams. In some cases, future expansion is contemplated even during the initial phase of a project. In other cases, it could be a necessity not foreseen during system design phase (Miller and Stöcker 1989; Brunetti et al. 2010).

Membrane system expansion is very easy, since this only requires the addition of identical modules. This is the advantage offered by the modularity of membrane units and the reduced equipment and control systems required for operating it. In comparison, considering the other reference technologies for gas separation, PSA and absorption systems can also be expanded, but it requires additional design considerations and adds cost in the initial phase of the project.

The cryogenic units cannot be expanded if it is not foreseen during the design phase. Generally they can be over-dimensioned, and a capacity increase is often obtained without modification to the cold box itself through addition of a tail gas compressor.

Effective Diffusivity

Renzo Di Felice

University of Genova, Genova, Italy

Effective diffusivity is a convenient parameter which is introduced when diffusion takes place in non-homogenous media. Consider, for example, the case where a species is diffusing through porous particles, such as reactant diffusing inside a catalytic solid. In this case, the molecules have to travel for a longer distance given that the pores of the catalytic particles are not straight, and moreover diffusion takes place over a smaller area due to the solid being wall impermeable. These effects are taken into account by defining an effective diffusivity as

$$D_{eff} = D \left(\frac{\varepsilon}{\tau} \right)$$

where ε is the particle void fraction and thereby takes into account the reduced flow area available and τ is the tortuosity which considers the longer distance traveled by the molecules. It should be stressed, however, that more often than not, the parameter inside the parenthesis is utilized as a fitting factor derived from experimental data rather than predicting factor from the solid physical characteristics. These result in the reported tortuosity factor, for example, to assume rather wild values, as high as ten, which are difficult to justify with geometrical arguments alone.

The concept of effective diffusivity is also applied for the case of species diffusing in heterogeneous media, such a polymer filled with a second, less permeable, material. Maxwell (1873) has obtained an exact expression, in the case of composite media filled with spheres, for the effective diffusivity given as

$$D_{eff} = D \frac{\frac{2}{D_s} + \frac{1}{D} - 2\phi \left(\frac{1}{D_s} - \frac{1}{D} \right)}{\frac{2}{D_s} + \frac{1}{D} + \phi \left(\frac{1}{D_s} - \frac{1}{D} \right)}$$

where D is the diffusion coefficient in the primary media, D_s the diffusion coefficient through the spheres, and ϕ the sphere volume fraction. For the limiting case of the spheres being completely impermeable, Maxwell expression simplify to

$$D_{eff} = D \frac{1 - \phi}{1 + \frac{\phi}{2}}$$

Various empirical expressions have been reported in literature in order to take into account the deviation from sphericity of the foreign material. Particularly simple and efficient is the expression proposed by Nielsen (1967):

$$D_{eff} = D \frac{1 - \phi}{1 + \frac{\alpha\phi}{2}}$$

where α is the dispersed material aspect ratio. Nielsen relationship has been shown to do a satisfactory job against experimental evidence (Di Felice et al. 2008).

Effectiveness Factor

Renzo Di Felice

University of Genova, Genova, Italy

The concept of effectiveness factor is utilized when the effect of diffusion on the overall rate of a reacting process wants to be taken into account. Let's consider a catalytic solid particle where a reaction takes place. For a species to react, it must, at the same time, diffuse inside the catalytic particle and react. It is intuitive that the diffusion step slows the overall process rate, and an effectiveness factor is defined as

$$\eta = \frac{\text{actual rate of process}}{\text{rate of process if diffusion were infinitely fast}}$$

This definition is equivalent to consider reactant concentration on any point in the catalytic particle equal to that at the external surface.

A rather straightforward mass balance allows the determination of the effectiveness factor for a single cylindrical pore where a first-order reaction is taking place on the wall:

$$\eta = \frac{\tanh\phi}{\phi}$$

where ϕ is the Thiele module defined as

$$\phi = L \sqrt{\frac{k}{D_{eff}}}$$

with L the pore length, k the chemical reaction kinetic factor, and D_{eff} the reacting species effective diffusivity.

As expected the effectiveness factor approaches 1 when Thiele module is very small, i.e., for very short pores or very slow reaction or very high diffusion coefficients. On the other hand, for very high value of Thiele modules, effectiveness factor approaches the inverse of the Thiele module.

The above result can be easily generalized for the case of flat plate by putting L equal to half the plate width, for the case of long cylindrical pellets by putting L equal to half the pellet radius, and to the case of spherical pellets by putting L equal to one third the sphere radius. Extension to kinetic different from the first order has been presented in literature, and a summary can be found, for example, in Satterfield (1991).

Electrical Double Layer

Karel Bouzek and Tomas Bystron

Faculty of Chemical Technology, University of Chemistry and Technology Prague, Technická 5, Prague 6, Czech Republic

An electrical double layer is usually considered to form at the phase interface between two electrically conducting media. In such a case, on one side of the interface, an excess of positive charge exists, which is counterbalanced by an identical excess of negative charge localized on the opposite side of the interface. The overall system charge is thus equal to zero. In membrane science, this definition has, to a certain degree, been modified, the reason being that membranes can be produced from a broad spectrum of materials, including (i) electronic conductors (e.g., metals), (ii) ionic conductors (e.g., O^{2-} -conducting ceramics), (iii) functionalized polymers providing ionic conductivity through the liquid filling the

Electrical Double Layer, Fig. 1 Schematic sketch of structure of the Electrical Double Layer for (a) functionalized and (b) nonfunctionalized membrane materials

void volume of the material (ion-selective membranes), and (iv) nonfunctionalized polymeric or ceramic membranes.

Whereas, in the first two cases, the traditional definition is valid, in the last two, the situation is different. This is due to the fact that the bulk membrane material is neither an electronic nor an ionic conductor. Hence the double layer only forms on one side of the phase interface. The Fig. 1 provides a schematic sketch of the two mentioned cases. In the case of functionalized materials, the charge-carrying groups covalently bound to the polymeric backbone are oriented towards the void volume of the membrane interior, thus forming an electrically charged film covering the phase interface on the side of the solution. The charge of this film is compensated by that of the mobile ions present in the solution and located close to the film (see Fig. 1a).

In the case of the non-functionalized materials, the surface charge fixed to the surface of the solid phase is formed by specific adsorption of ions of one sign. Both the sign of the adsorbed ions and the extent of the adsorption are determined by the properties of the membrane material. In this case, too, the fixed charge is compensated by the charge

of ions moving in the system and located close to the absorbed surface film (see Fig. 1b).

An electrical double layer significantly influences the properties of the membrane, mainly with respect to its transport properties and behavior under current load. In selected cases the surface of the membrane materials is modified to achieve the preferred adsorption and thus the required transport and properties, including selectivity.

Electrical Interactions in Membranes

Karel Bouzek

Faculty of Chemical Technology, University of Chemistry and Technology Prague, Technická 5, Prague 6, Czech Republic

In general electrical (electrostatic) interactions arise as a result of the interaction of electrically charged particles (charge carriers) with surrounding matter (electrically charged and neutral) (Stuart 1989). In the case of membranes, probably the most important interactions to consider are those between electrically charged bodies, such as ions dissolved in solution and ion-conducting, functionalized, or even inert membranes. In living systems the electrostatic interactions between the charged/polar and neutral/nonpolar side of a solute molecules with each other and with a solvent are responsible for the formation/assembly of monolayer and bilayer biological membranes and their functioning.

On the fluid side the charge carriers are typically mobile ions or colloidal particles of organic and inorganic nature. These carriers interact with the charge carriers fixed in the material of the membrane (see also the electrical double layer). The charge fixed in the membrane material is, in principle, of dual origin: (i) it comes from the component introduced and incorporated during its synthesis, and (ii) it is the result of the specific adsorption of ions on the surface of the solid phase. Electrostatic interactions between fixed and freely moving charge carriers are responsible not only for several phenomena characteristic of

membrane separation processes, such as the existence of Donnan potential, the selectivity of mass transport, or mass transport enhancement under current load by electroosmotic flux, but also for the existence of life itself. These facts document the importance of electrical interactions in membrane materials with respect to their transport properties.

Electrical Potential

Karel Bouzek and Tomas Bystron

Faculty of Chemical Technology, University of Chemistry and Technology, Prague, Technická 5, Prague 6, Czech Republic

Electric potential is a scalar physical quantity determined by the electric energy (or work in general) necessary to transfer a unit positive electric charge from infinity to the point of interest in a studied system. The point in infinity is formally chosen as a reference state characterized by zero electric potential. From this more or less abstract and intuitive definition of the reference state, it is apparent that the absolute value of electric potential is not available experimentally. However, it is possible to measure electric potential difference, known as voltage.

We can distinguish between outer (external) and inner (internal) electric potential. In the case of outer electric potential, the charge is transferred to the closest proximity of the external surface of the phase *P*. However, the distance from this surface has to be large enough to avoid the appearance of molecular and image forces. At the same time it should not cause any weakening of the electric interaction with the charge located on the internal side of the phase interface. The inner

electric potential is determined by the strength of the electric field in the interior of the phase P . It thus represents the work necessary to transport the charge from infinity to the phase P . The difference between the inner electric potential and the outer electric potential corresponds to the surface potential of phase P (Arthur and Alice 1997).

Electrical Work in Membranes

Karel Bouzek

Faculty of Chemical Technology, University of Chemistry and Technology Prague, Technická 5, Prague 6, Czech Republic

An electrical work is defined as the work connected with the charge carrier transport between two points in an electric field, i.e., from point of potential φ_1 to point of potential φ_2 . Thus, electrical work in membranes is the product of the transported electrical charge and the difference in electric potentials between which it has passed (Arthur and Alice 1997). Since the resistivity of the membrane can be approximated by ohmic resistivity, the electrical work dissipated in the membrane is equal to the ohmic potential loss in the membrane multiplied by the current load. Expressed alternatively, it is equal to the square of the current load multiplied by the ohmic resistivity.

Electrically membrane operations are typically limited to systems involving electrically charged particles. In such a case, the application of an electric field can often significantly enhance the ongoing process. In selected cases, it is the application of an external electric field that makes the desired processes possible at all. By applying an electric field, electrically charged particles are dragged in the direction determined by the polarity of their charge and the vector of the electric field. This movement is responsible for electric current flow through the system. Part of the electric charge carried by one type of particles corresponds to what is known as the transference number of the given particle. It is proportional to the particle mobility in the system and the electric charge it carries (Colin 1976).

In the case of membrane operations enhanced by an electric field, generally functionalized ion-selective membranes are considered. Electrodialysis and dialysis are typical representatives of an electrically enhanced and a nonenhanced process, respectively. Electrodialysis is used to desalinate a treated stream containing dissolved ions by transporting them, due to the action of the electric field, against the concentration gradient to the concentrate stream (Fernando et al. 2011). In the case of dialysis the situation is the reverse, since the dissolved species move in the direction of the concentration gradient away from the treated stream to the solution free of the removed components flowing along the opposite side of the membrane. It is thus clear that electrodialysis is typically a significantly more intensive process in terms of the desalination rate. At the same time, it produces a significantly lower volume of the stream carrying the removed components. The electric field thus enhances the intensity of the

mass flux during membrane processes involving charged species and makes it possible to transport the charged species against the concentration gradient. On the other hand, dialysis is not limited to charged particles.

Electrically enhanced membrane operations can also be carried out with nonfunctionalized membrane materials or with membrane materials carrying no fixed electric charge, electrofiltration being an example. Here, the applied electric field influences the membrane operation indirectly by preventing blockage of the membrane surface. This is ensured by the electrophoretic transport of the charged colloidal particles concentrated in the solution away from the surface of the filtering membrane, see also Electrofiltration.

It is, therefore, evident that the application of an external electrical field can significantly enhance or modify processes, including membrane operations.

Electrochemical Processing

Tanja Vidakovic-Koch

Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany

In electrochemical processing, electrical energy is supplied to or obtained from the electrochemical system in order for chemical production or energy conversion to take place (Bard and Stratmann 2007). The first group of processes, also called electrolytic, is not spontaneous. The second group of processes, called galvanic, is spontaneous and it delivers electrical energy. Electrolytic processes can be further divided into two categories: inorganic and organic. In inorganic electrochemical processing, important commodity chemicals such as sodium hydroxide, chlorine, and pure metals are produced. The major inorganic electrochemical processing technologies are chlor-alkali electrolysis and electrowinning of metals like aluminum or copper. Nowadays, hydrogen production by water electrolysis gets more on importance in context of chemical storage of renewable electrical energy (wind and photovoltaic) in hydrogen. The most significant commercial electroorganic synthesis is Monsanto's electrohydrodimerization (EHD) of acrylonitrile to adiponitrile. Adiponitrile has an importance in production of nylon 6-6. Examples of galvanic systems are fuel cells and batteries. The main "product" of galvanic systems is electrical energy.

Electrochemical systems have some intrinsic advantages over other types of chemical systems like better control of a reaction rate, operation at lower temperatures, and less environmental impact. They take place in an electrochemical reactor. The design of an electrochemical reactor is influenced by the state of aggregation of reactants (gas, liquid, or solid), necessity of reactants and/or products separation, required mass transport conditions, and electrode materials. If product or reactant separation is required, an electrochemical reactor must contain a separator, which is a membrane. Major requirements on a membrane are good separation efficiency, low electrical resistance, no electron conductivity, low cost, long operating life time, good dimensional stability, and resistance to plugging and fouling. In general permeable and semipermeable membranes have been applied in electrochemical processing. Permeable membranes are porous materials filled with liquid electrolyte which permit the bulk flow of liquid through their structure and are thus nonselective regarding transport of ions or neutral molecules. In electrochemical processes, these are also referred to as diaphragms. Permeable membranes can be made of inorganic and organic materials and composites. Examples of these materials are asbestos (chlor-alkali electrolysis), polymers like polyethylene and polypropylene (batteries), or composites like polymer (polypropylene)-modified asbestos. Semipermeable membranes permit the selective passage of certain species by virtue of molecular size or charge. In electrochemical processes, ion-conducting membranes (see solid electrolyte) are broadly applied. In general, ion-conducting membranes have higher separation efficiency and lower electrical resistance than diaphragms, but they are also more costly and impose higher requirements on system purity.

Electrochemical Regeneration

Tanja Vidakovic-Koch

Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany

In electrochemical regeneration electrical energy is applied to restore some important property, like adsorption capacity or catalyst activity of a technical system. Electrochemical regeneration relies on principles of electrochemistry and relates to electrochemical processing. Electrochemical regeneration is conveniently conducted in situ with an electron as only reagent requiring simple handling and equipment. A technical setup for electrochemical regeneration requires in general two electrodes, an electrolyte and a power supply. In addition a membrane can be added to the setup in order to separate anode and cathode department. Some examples of electrochemical regeneration are electrochemical regeneration of activated carbon-based adsorbents in wastewater treatment and regeneration of enzymatic cofactors in electroenzymatic processes.

Organic pollutants in wastewaters can be removed by adsorption using, e.g., activated carbon as an adsorbent. This process is normally operated using a batch of adsorbent with sufficient capacity to operate for many months before reaching saturation. Once loaded, adsorbent must be disposed or regenerated. One option for adsorbent regeneration is electrochemical regeneration (Brown et al. 2004). The loaded adsorbent is located in a form of a packed or fluidized bed in the anode (anodic regeneration) or cathode (cathodic regeneration) compartment of the reactor. The efficiency of the regeneration depends on the processing time, voltage gradient, an electrolyte, and a compartment. According to literature the efficiency of cathodic regeneration is higher than of anodic regeneration. The mechanism of electrochemical regeneration is ascribed at the first place to local pH changes close to anode or cathode. At the anode side due to oxygen evolution reaction a pH decrease can be expected, while at the cathode side due to hydrogen evolution pH

value will increase. This pH changes induce organic pollutants desorption. In the next step, dissolved pollutants can be oxidized at the anode. In the case of the cathodic regeneration they have first to mitigate from the cathode to the anode. This might be mass transfer controlled leaving some residues in the cathode, unless very large currents or long regeneration times are employed.

Further example of electrochemical regeneration is regeneration of enzymatic cofactors in electroenzymatic processes (Wichmann and Vasic-Racki 2005). Redox enzymes are very selective and specific catalysts, which can enable a number of partial oxidation or reduction reactions for industrial applications at mild conditions. Broader industrial application of redox enzymes has been so far hindered by their dependence on expensive cofactors (e.g., nicotinamide adenine dinucleotide (NAD)), which are consumed in the reaction (e.g., Eq. 1) and have to be regenerated for a process to be economical:

Electrochemical regeneration offers a possibility of cofactor regeneration. In this respect especially regeneration of NAD has been studied since NAD-dependent oxidoreductases are of great industrial interest. The electrochemical regeneration can be represented by this reaction:

This reaction is however not selective enough and the kinetics is very sluggish on most known electrode materials. Some improvements have been achieved by using surface-modified electrodes. Another strategy is to add an additional mediator according to

Electrochemical cofactor regeneration is still not a mature technology, and further improvements in electrode materials are needed to make this option feasible.

Electrochemistry

Tanja Vidakovic-Koch

Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany

Electrochemistry is a branch of chemistry which studies charge transfer processes across an electrified interface also called an electrochemical double layer (Bockris and Reddy 1988, Hamann et al. 2007). Applications of electrochemistry are broad including electrochemical processing, electroanalysis electrochemical sensors, electrochemical regeneration, and corrosion. In addition, many important processes in biological systems like photosynthesis and cell respiration are inherently electrochemical processes.

The main feature of an electrochemical system is a separation of ionic- and electronic flows. Ions are flowing through the electrolyte which is exclusively an ionic conductor, while electrons flow through an outer electrical circuit which is exclusively an electron conductor. These two flows are interconverted at the electrode/electrolyte interface across the electrochemical double layer by means of an electrochemical reaction. The potential difference in the electrochemical double layer is related to thermodynamics (Nernst equation) and kinetics (Butler-Volmer or Tafel equations) of an electrochemical reaction and it is a driving force for the electrochemical reaction to take place. This unique feature of electrochemistry makes easy to control the reaction rate by electrons at different energies.

Electrochemical processes can be spontaneous (Gibbs free energy, $\Delta G < 0$), called galvanic, and

nonspontaneous $\Delta G > 0$, called electrolytic. Instead in terms of Gibbs free energy, spontaneity of an electrochemical process can be expressed in terms of cell voltage, where a positive value stands for a galvanic system and a negative for an electrolytic. The relationship between the cell voltage and Gibbs energy is given by equation $\Delta G = -nFU_r$, where n stands for number of exchanged electrons, F for a Faraday constant, and U_r for an equilibrium cell voltage.

Many electrochemical systems require presence of separators. This is usually a membrane which can be a permeable, termed diaphragm, or semipermeable, termed membrane. The latter type usually in addition to separation serves as an electrolyte, so-called solid electrolyte in electrochemical systems. An example is ceramic yttria-stabilized zirconia (YSZ) membrane which has found an application in solid oxide fuel cells. The ionic conductivity of this material is provided by O^{2-} ions.

Electrodeionization

Karel Bouzek

Faculty of Chemical Technology, University of Chemistry and Technology Prague, Technická 5, Prague 6, Czech Republic

Electrodeionization represents a variant of electrodialysis, modified in order to allow treatment of low-salinity and low-conductivity media. This technique is typically applied to produce high-purity water suitable for use, for example, in energetics. It combines the advantages of ion exchange with those of electrodialysis.

This technology is based on an electrodialysis unit with a diluate and also, in selected cases, a concentrate chamber filled with ion-exchanger particles. They can be arranged as monopolar beds (formed by particles of one polarity ion exchanger), as layered beds (cation- and anion-exchanger particles filled separately in several alternating layers), or as a mixed bed (uniform mixture of both types of ion-changer particles). The ion-exchange phase takes on the role of electroconductive media, thus reducing ohmic drop in the dilute chamber. At the same time it provides a three-dimensional interface for the removal of traces of ions present in the solution. Two regions are typically distinguished in the electrodeionization operation: (i) ions removal and (ii) solvent splitting. Within the first region the electrodeionization unit works below mass transfer limitation. It means, flux of ions to the solution – ion exchanger interface driven by the current load used has a value well below mass transfer limitation in a dilute chamber. The function of the ion-exchange bed consists in providing a pathway for ions trapped in the dilute channel to the ion-selective membranes separating dilute/concentrate chambers. In a second domain, however, the current load exceeds limiting current density, i.e. limiting flux of ions present from solution to the solution – ion exchanger interface. In such a case sufficient number of ions to transport corresponding electrical charge is provided by decomposition (dissociation) of the solvent (typically water). In contrast to electrodialysis, this splitting does not take place only at the solution-membrane interface but also at the contact of the cation- and anion-selective phase (Alvarado and Chen 2014).

In the case of a concentrate chamber, the role of the ion-exchange phase again consists in reducing ohmic drop in the channel while maintaining the concentration of the ions in the liquid phase at a minimum to reduce back diffusion from the concentrate to the dilute chamber.

The quality of the stream produced is comparable to that of the ion-exchange process. The advantage of electrodeionization is that it is a continuous process that does not require a regular regeneration phase of operation. This feature of

electrodeionization has a further important advantage. It saves a significant amount of corresponding chemicals and reduces the salinity of the waste streams produced. Such technology is thus a suitable component for closed loop technologies which, on ending, discharge removed salts in the solid form and avoids production of contaminated liquid streams.

Electrodialysis

Heiner Strathmann
Universität Stuttgart, Institute of Chemical
Process Engineering Stuttgart, Baden-
Württemberg, Germany

The principle of electrodialysis is illustrated in Fig. 1 which shows a series of alternating anion- and cation-exchange membranes arranged between two electrodes. The membranes are separated by a spacer gasket and form individual cells, through which an electrolyte solution is pumped. When an electrical potential difference

between the electrodes is established, the cations migrate toward the cathode. They pass through the cation-exchange membrane, but they are retained by the anion-exchange membrane. Likewise the anions migrate toward the anode and pass through the anion-exchange membrane but are retained by the cation-exchange membrane. The overall result is that an electrolyte is concentrated in alternate compartments, while its ion content is depleted in the other compartments. In an industrial size electrodialysis stack, 100–400 cell pairs are arranged between the electrodes. Various spacer and stack constructions such as the so-called sheet flow are used in practical applications (Schaffer and Mintz 1966).

The concept of a sheet flow stack is illustrated in Fig. 2 which shows the arrangement of the spacers and membranes in a stack. The spacers not only separate the membranes and provide the proper mixing of the solutions in the cells, but in their frames, they also contain the manifolds for the two different flow streams in the stack.

Practical problems which affect the efficiency of electrodialysis are concentration polarization and membrane fouling. Concentration polarization which determines the so-called limiting current density is controlled by hydrodynamic parameters of the feed flow in the stack. Membrane fouling is controlled by a technique which is referred to as “clean in place” or electrodialysis reversal (Katz 1979).

The total costs in electrodialysis are the sum of the plant capital and the plant operating costs. The

Electrodialysis,
Fig. 1 Schematic diagram illustrating the principle of electrodialysis

Electrodialysis, Fig. 2 Schematic drawing illustrating the construction of a sheet flow stack design

capital related costs are proportional to the required membrane area for a given capacity plant and a for a given feed and product concentration. The operating costs are proportional to the required desalination energy which is the function of the transferred ions, i.e., the concentration difference between the feed and product ion concentration. The energy E^V required to desalinate 1 m^3 of water by electrodialysis is given by

$$E^V = \frac{Fr_{CP}^A}{\xi} i (C^f - C^p)$$

Here r_{CP}^A is the area resistance of the cell pair, which can be estimated from measurements of membrane resistance and conductivities of solutions, F is the Faraday constant, i is the current density, C^f and C^p are the feed and product water concentrations, and ξ is an efficient term which is generally close to 1.

Electrodialysis has advantages and limitations compared to other deionization processes such as reverse osmosis. A main advantage of electrodialysis compared to reverse osmosis is that very little feed pretreatment is required and higher brine concentrations can be achieved.

A major disadvantage especially for the production of potable water is the fact that only ions are removed, while uncharged components such as microorganisms or organic contaminants will not be eliminated. Another disadvantage of electrodialysis is the relatively high energy consumption when solutions with high salt concentrations have to be processed. Thus, electrodialysis can only be cost-effectively applied in water desalination in a certain range of feed water salt concentration and required product water (Strathmann 2010).

Electrodialysis with Bipolar Membranes

Heiner Strathmann

Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

The conventional electrodialysis can be combined with bipolar membranes and utilized to produce acids and bases from the corresponding salts. A bipolar membrane is a laminate of an anion on a cation-exchange layer. In this process monopolar cation- and anion-exchange membranes are installed together with bipolar membranes in alternating series in an electrodialysis

stack as illustrated in Fig. 1 which shows a typical repeating unit of an electrodialysis stack with bipolar membranes is composed of three cells, two monopolar membranes and a bipolar membrane. The outer cells of the repeating unit are fed with a salt solution, the inner cells with water, or a diluted acid and base. When an electrical potential gradient is applied across a repeating unit, protons and hydroxide ions which are generated in the bipolar membrane generate with the cations and anions removed from the salt solution, an acid and a base on either side of the bipolar membrane. The process design is closely related to that of the conventional electrodialysis using the sheet flow stack concept (Liu et al. 1977; Simons 1993).

The utilization of electrodialysis with bipolar membranes to produce acids and bases from the corresponding salts is economically very attractive and has a multitude of interesting potential applications in the chemical industry as well as in biotechnology and water treatment processes. Its key component is the bipolar membrane. The bipolar membrane schematically illustrated in Fig. 2 consists of a laminate of an anion- and a cation-exchange membrane with a 4–5 nm thick catalytic transition layer in between. In Fig. 2 this transition

Electrodialysis with Bipolar Membranes, Fig. 1 Schematic drawing illustrating the principle of the electrodialytic production of an acid and a base from the corresponding salt with bipolar membranes. Repeating

cell unit consisting of a cation-exchange membrane (cm), a bipolar membrane (bpm), and an anion-exchange membrane (am)

Electrodialysis with Bipolar Membranes, Fig. 2 Schematic drawing illustrating the electroalytic water dissociation in a bipolar membrane with water diffusing into the reaction region between the cation- and anion-exchange layers of the membrane and protons and hydroxide migrate to the corresponding electrode

layer has been artificially magnified. Water is diffusing through both membrane layers into the transition layer where it gets electro-catalytically dissociated into H^+ - and OH^- -ions, which migrate toward cathode and anode into the outer solutions.

The energy required for the water dissociation can be calculated from the Nernst equation for a concentration chain between solutions of different pH-values. It is given by:

$$\Delta G = F\Delta\varphi = 2.3RT\Delta\text{pH}$$

Here ΔG is the Gibbs free energy and ΔpH and $\Delta\varphi$ are the pH-value and the potential difference between the two solutions separated by the bipolar membrane. For 1 mol/L acid and base in the two phases separated by the bipolar membrane, ΔG is 0,022 kWh/mol and $\Delta\varphi$ is ca. 0,83 V at 25 °C. Compared to the ohmic potential drop over the membranes, the required potential drop for water splitting in the transition layer is much more pronounced. The determination of the costs for the production of acids and bases from the corresponding salts follows the same general procedure as applied for the cost calculation in electrodialysis desalination. The overall costs are the investment-related costs and the operating costs. The investment-related costs are dominated by the membrane costs and are proportional to the

required membrane area for a given capacity plant. They are a function of the current density applied in a given stack operation. A unit cell contains a bipolar membrane, a cation- and an anion-exchange membrane. The bipolar membrane is rather expensive, and its useful life time as well as that of the anion-exchange membrane is rather limited in strong bases. The operating costs in electrodialysis with bipolar membranes are strongly determined by the energy requirements which are composed of the energy required for the water dissociation in the bipolar membrane and the energy necessary to transfer the salt ions from the feed solution and protons and hydroxide ions from the transition region of the bipolar membrane into the acid and base solutions. The energy consumption due to the pumping of the solutions through the stack can generally be neglected. Since bipolar membranes became available as commercial products, a large number of applications have been identified and studied on a laboratory or pilot plant scale. However, in spite of the obvious technical and economical advantages of the technology, large-scale industrial plants are still quite rare (Gineste et al. 1996). The main reasons for the reluctant use of bipolar membrane electrodialysis are poor membrane stability at very high or low pH-values and insufficient permselectivity at high ion concentrations, which results in a substantial product salt contamination, low current efficiency, and short membrane life. Nevertheless, there are a number of smaller-scale applications in the chemical process industry, in biotechnology, in food processing, and in wastewater treatment.

Electrodriven Membrane Processes

Seung-Hyeon Moon

School of Environmental Science and Engineering, Gwangju Institute of Science and Technology (GIST), Gwangju, South Korea

Introduction

Electrolyte membranes or ion exchange membranes (IEMs) are ion-selective membranes for separation or charge transfer through the membranes. Electrodriven membrane processes employ IEMs under an electric field to perform (i) mass separation for concentration or dilution of ions in aqueous phase; (ii) chemical synthesis with an electrochemical reaction, such as chlorine-alkaline electrolysis and production of hydrogen via water electrolysis; and (iii) energy conversion and storage involving the conversion of chemicals into electrical energy and vice versa. Non-charged porous membranes are also used in some energy conversion processes to separate anolyte and catholyte solutions.

Separation Processes

Applications of the first type are mainly found in separation of ionic species under an electric field. Cations move toward a cathode and permeate through a cation exchange membrane while anions move toward an anode and permeate an anion exchange membrane. Due to rejection of non-permeable ion by the membranes, electrolytes are concentrated or diluted in a compartment. Typical processes in this category are electrodialysis, bipolar membrane electrodiagnosis, electrodeionization, and membrane capacitive deionization. Without an electric field, diffusion dialysis enables to purify acid or base solutions containing metallic contaminants.

Electrodialysis (ED) is an electrochemical separation process using an electrical potential as a driving force. Electrodialysis systems typically consist of a cell arrangement with a series of

alternating anion and cation exchange membranes between an anode and a cathode. Within ion exchange membranes, charged groups are attached to the polymer backbone of the membrane material. These fixed charged groups partially or completely exclude ions of the same charge (co-ions) from the membrane, so that an anion exchange membrane (AEM) with fixed positively charged groups excludes positive ions but is freely permeable to negatively charged ions, referred to as counterions. Similarly, a cation exchange membrane (CEM) with fixed negatively charged groups is freely permeable to positively charged ions. When an aqueous salt solution is circulated in the cell under an electrical potential, the positively charged cations migrate toward the cathode and the negatively charged anions toward the anode. The overall result is a potential drop across the cell pairs as well as a change in the ion concentration in alternate compartments. The depleted solution is generally referred to as the diluate and the concentrated solution as the concentrate. Electrodialysis is used for desalination of various salt solutions including seawater as well as production of table salt (Fig. 1).

A **bipolar membrane (BPM)** in which the anion- and cation-exchangeable layers (AEL/CEL) are adjoined together easily splits water molecules into protons and hydroxyl ions under a reverse bias condition. Accordingly introduction of inorganic substances into the bipolar membrane is known to be an effective technique for generation of acid and base. Two or three compartment stack configurations may be chosen depending on the product specification, i.e., CEM-BPM, AEM-BPM, or CEM-BPM-AEM. It is expected that water-splitting electrodialysis using bipolar membrane can make zero-emission possible and be applied as a clean technology by recycling salt by-products after splitting to acid and base. Developments of high-performance bipolar membranes further expand use of bipolar membrane electrodialysis in chemical, biochemical, and environmental industries (Fig. 2).

Electrodeionization (EDI) or continuous electrodeionization (CEDI) is a hybrid separation process that removes ionized species from liquids using electrically active media and an electrical

Electrodriven Membrane Processes, Fig. 1 An Electrodialysis Cell

E

Electrodriven Membrane Processes, Fig. 2 A Bipolar Membrane Electrodialysis Cell

potential activating ion transport. The electrically active media, such as an ion exchange resin in CEDI devices, may function to alternately collect and discharge ionized species or to facilitate the transport of ions continuously by ionic or electronic substitution mechanisms. Unlike an ion exchange process, CEDI does not require chemicals to regenerate the ion exchange resin or concentrate the wastewater. In a CEDI system, the ion exchange resin bed plays a major role in the reduction of the high electrical resistance in the diluate compartment, while the ion exchange membranes lead to depletion and concentration of the solutions in the diluate and concentrate compartments, respectively. The CEDI process is capable of achieving high levels of purification

and the concentration of dissolved ionic solutes at a relatively low salt concentration (Fig. 3).

Membrane capacitive deionization (MCDI) is an advanced capacitive deionization (CDI) with the help of ion exchange membranes. A CDI system is operated by adsorption and desorption of ions on carbon electrodes. When an electric potential is applied to CDI cells, charged ions in contaminant water are adsorbed onto the surface of charged electrodes and forms an electric double layer due to the charged electrode and adsorbed ions, producing purified water. Often CDI leads to a higher energy consumption and a lower operation efficiency due to mobility of unwanted ions. To avoid this phenomenon, ion exchange membranes are introduced to CDI for ion selectivity,

Electrodriven Membrane Processes, Fig. 3 An Electrodeionization Cell

which is called membrane CDI (MCDI). A MCDI employs two types of ion exchange membranes, i.e., cation exchange and anion exchange membranes. The AEM and CEM are positioned in front of the positively and negatively charged electrodes, respectively. While counterions are attracted onto the electrode surface, simultaneously co-ions expelled from the counter electrode. The selectivity of ion exchange membranes prevents reverse adsorption and prohibits the mobility of unwanted ions.

Diffusion dialysis is a membrane separation process in which transport of selective ions is driven by a concentration difference over an ion exchange membrane. The diffusion dialyzer for acid recovery consists of a multitude of compartments made of gaskets arranged alternately with anion exchange membranes, which allow acids to permeate but retain metal salts. The gasket surrounds a meshlike spacer by which mixing in a

compartment is enhanced. The acid feed enters the bottom of every alternate compartment, as water is fed from the upper part of the stack to contact the acid feed counter currently. Permeate acids are collected from the bottom of the permeate compartment as purified acid product. The depleted feed flows out of the upper part as an effluent containing high concentrations of metal salts and a low concentration of remaining acid. Similarly a cation exchange membrane is used to recover base from metal salts.

Chemical Synthesis Processes

Applications of the second types are electrolysis processes to generate chemicals by electrode reactions and ion substitution through membranes.

A **chlor-alkali process** involves electrode reactions for the electrolysis of NaCl solution.

Electrodriven Membrane Processes, Fig. 4 A Membrane Capacitive Deionization Cell

The process produces caustic soda (NaOH) and chlorine (Cl_2) that are used in a wide range of industries. The most common chlor-alkali process is the electrolysis of aqueous sodium chloride in a membrane cell. The membrane is a cation permeable one which allows positive ions to pass through it. That is, the only the sodium ions from the NaCl solution may pass through the membrane and not the chloride ions. The advantage of the membrane process is that the sodium hydroxide solution is formed in a cathode compartment which is not contaminated with NaCl solution. Also purified NaCl should be supplied to obtain pure NaOH solution. Chlorine is generated at anode by oxidation of chloride ion. As a clean energy, hydrogen had been drawing more attention. One of hydrogen sources is electrolysis of water, splitting water to hydrogen and oxygen. Various catalysts and energy sources are investigated to improve the efficiency as a reverse process of a fuel cell.

Electro-ion substitution reaction can be carried out in an ED stack in which membranes are all of the same kind, either anion or cation exchange membranes. In a unit cell consisting of two compartments with CEMs, acid and feed streams flow. When an electric current is supplied to the stack, protons in the acid stream (HX) are transported to the feed stream (NaA) and convert the negatively charged organics (A^-) to free acid (HA). As a result the inorganic cations in the feed stream, in this case sodium ions, are transported to the acid compartment to meet the electroneutrality (NaX) in the feed stream, completing an ion exchange reaction,

$\text{NaA} + \text{HX} \rightarrow \text{HA} + \text{NaX}$. A four-compartment double decomposition cell consists of a series of anion and cation exchange membranes arranged in an alternating pattern between anode and cathode. When the cell is operated with four different streams, ion substitution or salt metathesis reaction occurs, $\text{AX} + \text{BY} \rightarrow \text{AY} + \text{BX}$ (Fig. 4).

Energy Conversion Processes

Applications of the third types are found in various energy conversion and storage systems where charge carriers are selectively permeate through a membrane. Charge carriers are generated from electrode reactions or initially supplied as supporting electrolytes. When charge carriers move between anolyte and catholyte without mixing of active materials, a separator type membrane may be used. This type of applications includes fuel cell, lithium ion battery, redox flow battery, reverse electrodialysis, etc.

Polymer electrolyte fuel cells (PEFCs) are commonly considered to be one of the most likely potential alternative power sources due to their convenient operating temperature, high-energy conversion efficiency, and ease of integration into hybrid systems. Electricity is generated by potential difference between anode where hydrogen or fuel is oxidized to proton with the help of catalyst and cathode where oxygen is reduced and reacts with proton. A polymer electrolyte membrane is placed between the anode and cathode catalysts to insulate between electrodes. Polymer

Electrodriven Membrane Processes, Fig. 5 A
Diffusion Dialysis Cell

electrolyte membrane (PEM) sandwiched with two catalyst layers is called a membrane-electrode assembly (MEA). Perfluorinated sulfonic acid membranes such as Nafion[®], Flemion[®], Aciplex[®], and Dow[®] series have been widely used due to their high proton conductivity and good thermal and chemical stability. Hydrocarbon-based membranes, however, are generally less stable and subject to fast degradation, yet to be improved for practical applications. Recent efforts have focused on the commercialization of PEFCs in a range of applications, including use in portable devices, residences, stationary applications, and vehicles (Fig. 5).

A **lithium ion battery** is a rechargeable battery in which lithium ions move between anode and cathode with redox reactions during charge and discharge cycles. A separator is required to prevent mixing of anolyte and catholyte while lithium ions permeate freely in electrolyte solution. Often the separator is prepared as a multilayer porous membrane due to requirement of shutdown and meltdown. The lithium ion battery is rapidly growing due to the widespread use of wireless electronics such as cell phones and laptop computers. Moreover, concerns about global warming and oil shortages have led to the development of high energy density Li ion batteries

used for energy storages and electric vehicles. In these applications, safety is a key parameter. The safety of battery is closely linked to the battery separator absorbing a highly flammable liquid electrolyte. Although typical separators based on semicrystalline polyolefin materials such as polyethylene (PE) and polypropylene (PP) are mechanically strong and relatively inexpensive, their low melting temperature possibly causes physical contact between two electrodes over 180 °C. The physical contact triggers thermal runaway, which results in explosive burning of the highly flammable liquid electrolyte (Fig. 6).

A **redox flow battery** is an energy storage device in which potential difference of a redox couple generates (discharge) or stores (charge) electric energy. Positive and negative electrolytes are stored separately and the electrolyte solutions are fed into a cell for energy conversion. A variety of membranes are used for RFB systems depending on the charge carrier, electrolyte solvent, and redox couple. Membranes must possess two main properties: preventing the undesirable cross-mixing of the negative and positive electrolytes to minimize self-discharge, while selectively conducting the charge carrier ions through the membrane to complete the redox circuit during the passage of current. Typically monovalent

Electrodriven Membrane Processes, Fig. 6 Electro-Ion Substitution Cell

E

Electrodriven Membrane Processes, Fig. 7 A Salt Methathesis Cell

selective cation exchange membrane or a thin anion exchange membrane is used to prevent crossover of the cationic redox couples when proton is a charge carrier. A RFB is a promising technology due to several advantages such as its large capacity, convenient operating temperature, long cycle life, and so on. On the other hand, the use of an aqueous electrolyte severely restricts the energy density as is determined by the cell potential that is constrained by the electrochemical stability window of water. Along with commercialization of aqueous RFBs, nonaqueous RFBs which can offer a higher density have drawn considerable interest from energy storage

researchers. Furthermore, nonaqueous organic electrolytes provide a wider potential window of operation due to the high solubility of various metal–ligand complexes in an organic solvent. Nonaqueous RFB systems require ion exchange membranes or non-charged porous membranes depending on the electrochemical properties and molecular size of charge carriers employed (Fig. 7).

Reverse electrodialysis (RED) is an ion exchange membrane process for renewable energy generation. Electric potential occurs as a result of Donnan equilibrium where two solutions containing permeable ions are separated by a

Electrodriven Membrane Processes, Fig. 8 A
Polymer Electrolyte Membrane Fuel Cell

corresponding ion exchange membrane. Using a similar cell structure to electrodialysis, electricity can be generated by diffusion of ions using concentrated salt solution and diluted solution, called reverse electrodialysis (RED). Typically seawater and river water may be used as feed solution in a modified electrodialysis cell. Other salinity gradient power generation is pressure-retarded osmosis using pressure difference due to the concentration difference across an osmotic membrane including a polymer electrolyte active layer (Fig. 8).

Perspectives

Electrodialysis has been studied and industrialized for nearly a century as a leading electrodriven membrane process. Along with the appearance of advanced ion exchange membranes, various separation and reaction processes are following electrodialysis in many industries as demands for compact and environmentally friendly processes are growing continuously. Last several decades energy-related electrodriven membrane processes are growing rapidly with the help of membranes as a key component. Many membranes originally developed for separation processes have expanded their applications for energy conversion and storage. Accordingly the membranes should be characterized in terms of electrochemical properties to improve the performance appropriately,

i.e., ionic conductivity, transport number, oxidative stability, and power density.

Electro-Fenton Process

Marc Cretin^{1,2} and Mehmet A. Oturan³

¹Institut Européen des Membranes, ENSCM-UM-CNRS (UMR 5635), Université de Montpellier, Montpellier Cedex 5, France

²National School of Chemistry of Montpellier, University of Montpellier, Montpellier, France

³Laboratory of Earth Materials and Environment, University Paris-Est, Marne La vallée, Champs-sur-Marne, France

The electro-Fenton process is one of the most popular electrochemical advanced oxidation processes. As all the advanced oxidation process (AOPs), electro-Fenton (EF) process is based on the in situ production and reactions of the hydroxyl radicals ($\cdot OH$), the second powerful oxidant (after fluorine) with $E^0(\cdot OH/OH^-) = 2.80 \text{ V/SHE}$ and a very reactive species (Brillas et al. 2009; Oturan

and Aaron 2014). $\cdot\text{OH}$ is able to mineralize any organic pollutants and therefore used in AOPs in order for destruction of persistent organic pollutants.

Contrary to anodic oxidation process (Panizza and Cerisola 2009) in which $\cdot\text{OH}$ s are produced at anode surface from water oxidation (Panizza and Cerisola 2009), in the EF process, $\cdot\text{OH}$ s are generated in the bulk of solution from electrochemically assisted Fenton's reactions:

In the classical Fenton process, the Fenton's reagent ($\text{H}_2\text{O}_2 + \text{Fe}^{2+}$) is added externally to the reaction medium. This leads to the formation of $\text{Fe}(\text{OH})_3$ sludge and promotes wasting reactions that decrease process efficiency. EF process has a great advantage to generate in situ H_2O_2 (from two-electron reduction of O_2) and regenerate ferrous iron ions (from initially added catalyst) as schematized on the following electrochemical reactions:

There is no accumulation of Fe^{3+} and other reagents (H_2O_2 and Fe^{2+}), so sludge formation occurs and parasitic reactions are minimized to enhance mineralization (transformation of organics to CO_2 and water) efficiency.

In the case of using a high O_2 evolution anode such as boron-doped diamond (BDD) film anode, $\cdot\text{OH}$ are formed simultaneously at the anode as well as in the bulk solution from the electrogenerated Fenton's reagent. The oxidation power and mineralization efficiency are extremely high (Dirany et al. 2010).

The $\cdot\text{OH}$ thus formed by the process in a continuous and catalytic way will react with the organic pollutants present in the medium until

their mineralization, i.e., transformation to CO_2 , H_2O , and inorganic ions.

This EF process has been shown to be more efficient and cost-effective than some widely AOPs such as Fenton oxidation and ozonation for the treatment of organic pollutants species (Brillas et al. 2009; Oturan and Aaron 2014). It was successfully applied to the removal of toxic and persistent organic pollutants from water such as synthetic dyes, chlorinated aromatics, chloro-/nitrophenol herbicides, insecticides, fungicides and other pesticides, and pharmaceutical and personal care products. The results of these studies have shown that the EF process using a large surface area carbon-felt cathode is a very promising technology due to its simplicity, low cost, and outstanding performance, which is mainly due to the quick and efficient cathodic regeneration of the Fe^{2+} catalyst.

Electrofiltration

Karel Bouzek

Faculty of Chemical Technology, University of Chemistry and Technology Prague, Technická 5, Prague 6, Czech Republic

Electrofiltration represents a modification of dead-end membrane micro- or ultrafiltration. It targets a significant reduction of the filtration

Electrofiltration,

Fig. 1 Schematic sketch of electrofiltration principle, F_w stands for driving force due to the friction between the particle and flowing solvent molecules and F_e stands for driving force resulting from action of the applied electric field E on the particle carrying electrical charge

time and focuses especially on the filtration and/or concentration of colloidal substances that otherwise rapidly build up a deposit of colloidal particles on the surface of the membrane, which strongly hinders permeation of the fluid phase. The basic principle is that colloidal particles usually carry an electric charge. Hence, by applying an appropriate electric field, colloidal particles can be moved in the direction opposite to the fluid flow, thus keeping the surface of the filtrating membrane free of the deposit (Henry et al. 1977). A schematic sketch of this arrangement is shown in the Fig. 1.

As the filtrating membrane remains unimpeded by a deposit of colloidal particles, the pressure drop across it remains relatively low. In contrast, the separator covered by the layer of colloidal particles attracted by the electric field does not permit a significant fluid flow. This results in a reduction of the shear stress forces in the deposited film of separated colloid. These facts make electrofiltration especially promising for the separation of biotechnology-derived products, the reason being that such products are typically sensitive to high shear stress forces while at the same

time they are electrically charged. The mild conditions of electrofiltration thus enable their properties to be preserved during the process of their separation (Gözke and Posten 2010).

Electrolyzers

Antonino Salvatore Arico
CNR-ITAE Institute, Messina, Italy

One of the main processes occurring in an electrolyzer device is the water electrolysis. Electrolysis of water is the dissociation of water molecules into hydrogen and oxygen gases. For this

process, in the presence of liquid water at 298 K and 1 bar, ΔG° is 237 kJ mol^{-1} (corresponding to $\sim 1.23 \text{ V}$), ΔS° is $163 \text{ J mol}^{-1} \text{ K}^{-1}$ ($T\Delta S^\circ \sim 0.25 \text{ V}$), whereas ΔH° is 286 kJ mol^{-1} . The thermoneutral potential at which this reaction occurs in the absence of external heat supply is $E_{\text{th},\Delta H} = 1.48 \text{ V}$ (upper heating value $3.54 \text{ kWh}\cdot\text{Nm}^{-3} \text{ H}_2$) (Millet et al. 2011). If steam is fed to the device, the reaction enthalpy is reduced by $\sim 40 \text{ kJ mol}^{-1}$ corresponding to the vaporization enthalpy. Water electrolysis is traditionally carried out in alkaline media with several commercial electrolyzers available on the market. Water electrolyzers using a solid polymer electrolyte are less common and generally use expensive materials such as noble metal electrocatalysts and Nafion membranes (Barbir 2005; Siracusano et al. 2010). Polymer electrolyte membrane (PEM) electrolyzers represent a viable alternative to alkaline electrolyzer using KOH or NaOH as electrolytes for hydrogen generation. The advantages of SPE water electrolyzers especially concern with increased safety, high energy density, and low maintenance. In the PEM water electrolyzer, water is usually supplied to the anodic compartment where oxygen evolution occurs, whereas hydrogen is produced at the cathode by protons transported through the protonic membrane (Fig. 1). The electrodes are usually composed of a platinum electrocatalyst for hydrogen evolution, whereas metal oxides (e.g., IrO_2 , RuO_2 , etc.) are used for the anode due to their enhanced activity and stability than Pt for this reaction (Marshall et al. 2007; Siracusano et al. 2010). The performance of an SPE electrolyzer is strongly related to the characteristics of the membrane and electrode assembly (MEA) where the electrochemical reactions take place at triple-phase boundary. Therefore, the interface between solid polymer electrolyte and electrocatalyst layers should be characterized by a suitable extension; furthermore, the contact resistance between the catalytic layer and the membrane should be as low as possible. Generally, Nafion[®] membrane is used as conducting polymer electrolyte in PEM electrolyzer systems. However, low levels of H_2 and O_2 crossover are necessary for PEMWE application due to the high-

Electrolyzers, Fig. 1 Principle of operation of a PEM water electrolysis cell

pressure operation that may reach 50–100 bars. Thus, a proper thickness is necessary for the polymer electrolyte separator (around $100 \mu\text{m}$). For high-pressure operation in PEM electrolyzers, reinforced PFSA membranes provide a proper combination of good conductivity and high mechanical strength.

Electromembrane

G  rard Pourcelly

Institut Europeen des Membranes, CC 047,
Universite Montpellier II, Place Eugene Bataillon,
Montpellier, France

Electromembrane or “charged membrane” stands for ion-exchange membrane [IEM]. They are used in a number of processes which are rather different in their basic concept, their practical applications, and their technical relevance (Strathmann 2004). All IEM separation processes are based on the same fundamental principle which is the coupling of the transport of electrical charges, i.e., an electrical current with a transport of mass, i.e., cations or anions, through a permselective membrane due to an externally applied or internally generated potential gradient. There are two types of IEM: (i) monopolar and (ii) bipolar membranes.

Monopolar membranes are either cation-exchange membranes which contain negatively charged groups fixed to the polymer matrix or anion-exchange membranes which contain positively charged groups fixed to the polymer matrix.

In a cation-exchange membrane, the fixed negative charges are in electrical equilibrium with mobile cations (counterions) in the interstices of the polymer as shown in Fig. 1 (Strathmann 2010). In this case, the mobile anions are referred to as coions. They are more or less excluded from the polymer matrix because of their electrical charge which is identical to that of the fixed ions (Donnan exclusion (Donnan 1911)). Thus, the selectivity of an IEM results from the exclusion of coions from the membrane phase. The properties of IEM are determined by different parameters such as the density of the polymer network, the hydrophobic/hydrophilic character of the polymer matrix, the nature and the ratio of fixed ion-exchange groups, the cross-linking ratio, etc.

The most desired properties of IEM are (i) high chemical and thermal stabilities, (ii) high mechanical and dimension stabilities, (iii) high permselectivity, (iv) low electrical resistance, (v) and a low cost.

Bipolar membranes (BPMs) are composed of two layers of ion exchangers joined by a hydrophilic junction (Pourcelly et al. 2009). The diffusion of water from both sides of the BPM allows its dissociation under the electrical field to generate protons and hydroxyl ions, which further

E

Electromembrane, Fig. 2 Principle of a bipolar membrane. *Left hand:* water dissociation under electrical field. *Right hand:* the two ion-exchange layers bearing fixed anion- or cation- exchange groups

migrate from the junction layer through the cation- and anion-exchange layers of the BPM as depicted in Fig. 2. The requirements for suitability of BPM include that for monopolar membranes but also an experimental potential to achieve the water-splitting capability as close as possible as the theoretical value equal to 0.83 V at 25 °C.

Nowadays, superior styrene-divinylbenzene copolymer membranes can be easily purchased, perfluorinated membranes with great chemical stability are on the market, and BPM with an industrial-scale lifetime (>20,000 h) is available.

Electromembrane Processes

Gerald Pourcelly

Institut Europeen des Membranes, CC 047,
Universite Montpellier II, Place Eugene Bataillon,
Montpellier, France

Electromembrane processes involve ion-exchange membranes. They can be divided into three types: (i) Separation of components such as salts or acids and bases from electrolyte solutions. In this case, the driving force for the ion transport across the membrane is an electrical potential as in electrodialysis or a concentration gradient as in both diffusion dialysis and Donnan dialysis. (ii) The second type of processes involves an electrochemical reaction producing chemicals such as chlorine, acids and bases, or organic and inorganic compounds. The most known process of this type is the chlorine-alkali production where the ion-exchange membrane is the key component. (iii) The third type of ion-exchange membrane processes involves the conversion of chemical into electrical energy and vice versa. The solid polymer electrolyte fuel cell is the most significant application (Strathmann 2004).

Electromembrane Processes, Fig. 1 Scheme of a conventional two-compartment electrodesialysis stack (C): concentrate, (D): diluate compartments

(i): In dialysis, the driving force for the component transport is a difference of concentration between the two solutions separated by a membrane. In diffusion dialysis and Donnan dialysis the driving force is also a concentration gradient but the membrane is carrying anions or cations according to its permselectivity. Diffusion dialysis with anion exchange membranes is used on a large scale to recover acids from pickling solutions (Kobuchi et al. 1987). Donnan dialysis is used for water softening or for recovering organic acids from their salts (Kliber and Wisnieski 2011).

Electrodialysis (ED) is used to transport salt ions from one solution through ion-exchange membranes to another solution under the influence of an applied electric potential difference. The elementary cell consists of a feed (diluate) compartment and a concentrate (brine) compartment formed by an anion exchange membrane and a cation exchange membrane placed between two electrodes. In almost all practical ED processes, multiple ED cells (few hundreds) are arranged into a configuration called an ED stack Fig. 1.

Conventional ED is used mainly for desalination of saline solutions (chemicals) or milk whey (food industry). It can be combined with bipolar membranes (bipolar membrane electrodialysis)

and used to produce acids and bases from their corresponding salts, Fig. 2. This process is economically very attractive and has several interesting potential applications mainly in food industry, fine chemicals, or biotechnologies (Pourcelly et al. 2009).

(ii): The most known membrane electrolysis processes are for the production of chlorine and caustic soda (Pletcher and Walsh 1990) or special organic compounds (Sata 1991). In the chlorine-alkali process, the cells are arranged in a similar way as in an electrodesialysis stack but in two different configurations using monopolar or bipolar electrodes. Due to the severe operating conditions (80 °C, 35 wt% NaOH, wet chlorine), the membrane is a composite structure of sulfonated and carboxylated perfluorinated reinforced polymers.

(iii): Ion-exchange membranes are used today also as key components in energy storage and conversion systems such as batteries and fuel cells. A fuel cell is an electrochemical reactor in which energy is converted into electrical energy. Generally fuel cells are fed with hydrogen which is transformed into protons at a catalytic anode with electrons. Protons then migrate across a proton conducting membrane and combine with oxygen to produce water at the catalytic cathode (Lucia 2014).

Electroosmosis

Karel Bouzek

Faculty of Chemical Technology, University of Chemistry and Technology Prague, Technická 5, Prague 6, Czech Republic

Electroosmosis is the term used for the convective flow of a solution containing charge carriers, e.g., in the form of dissociated salts, through the pores or structure of a material with an electrically charged internal surface. In the field of membrane processes, this phenomenon is typically discussed in connection with the utilization of ion-selective membranes under current load. However, it can potentially occur in any membrane material. The schematic sketch of the principle of electroosmotic flux initiation in an ion-selective membrane pore (void space) is shown in Fig. 1.

The driving force of electroosmotic flux is the electric field. Flux velocity is directly proportional to the hydraulic permeability of a membrane and

Electronic and Ionic Conductivity

► Mixed Conducting Membranes

Electroosmosis, Fig. 1 The schematic sketch of a principle of electroosmotic flux initiation in the membrane with an electric charge carriers fixed on the pore (void fraction) wall

indirectly proportional to the viscosity of the pore fluid. The latter parameter represents an excess of free charge carriers of one sign in the bulk of the pore fluid. An excess of one-sign charge carriers is possible on account of an intrinsic property of an ion-selective membrane, i.e., the presence of charge-carrying functional groups in the membrane structure. These ion groups are bonded by a covalent bond to the backbone of the membrane material. They are thus fixed and immobilized in the structure. In the case of conventional membrane materials, the role of fixed charge can be carried out by ions specifically adsorbed on the pore walls or along the backbone of membrane materials. The charge carried by functional groups and/or adsorbed in the internal structure of the membrane has to be compensated by an excess charge of opposite sign present in the pore fluid. The electroosmotic convective flow of the pore fluid is induced by friction force between the solvated mobile charge carriers (ions) moving under the action of the electric field and the surrounding liquid phase molecules (Squires and Bazant 2004).

Electroosmotic flux represents one of the mechanisms of mass transfer through an ion-selective membrane. Its significance increases with increasing current load and, thus, the intensity of the electric field applied across the membrane (Fila and Bouzek 2008).

Electro-osmosis is the movement of liquid in response to an applied electric field across a conduit such as a membrane, capillary tube, microchannel, or porous material.

The application of an external electric field near a solid/liquid interface may result in the motion of liquid with respect to an adjacent charged surface. These associated effects are known as electrokinetic phenomena (Hunter 1981), first observed by Reuss in 1808 (Reuss 1809). Electrokinetic phenomena include electro-osmosis, electroacoustics, electrophoresis, diffusiophoresis, streaming potential, zeta potential, and sedimentation potential. The earliest experiments on electrokinetic phenomena focused on electro-osmosis because these are the easiest to conduct (Wall 2010). Early investigators included Wollaston, Porrett, Napier, Faraday, and Daniell.

Electroosmosis, Overview of,

Fig. 1 Schematic representation of electro-osmosis in a membrane pore, showing the effect of the electric field on the electric double layer (EDL) and the resulting drag on the bulk fluid

In electro-osmosis, the bulk fluid moves relative to a charged surface due to an external electric field.

The chemical equilibrium between a solid surface (such as a membrane) and a fluid containing charged species typically leads to the interface acquiring a net fixed electrical charge (most often negative for membranes), characterized by the zeta potential (ζ). The presence of co-ions (similarly charged ions) and counterions (oppositely charged ions) results in attraction and repulsion of ions in the vicinity of a charged surface. This phenomenon, coupled with the random thermal motion of the ions, creates an electric double layer (EDL) or Debye layer in the region near the interface. Electroneutrality is not maintained within the EDL, because there is an excess of counterions compared to co-ions in order to neutralize the surface charge (Probstein 2005). When an electric field is applied to the fluid, the net charge in the electrical double layer is induced to move by the resulting Coulomb force. The movement of ions drags bound solvent, causing bulk fluid motion due to momentum transfer, as depicted in Fig. 1. The resulting flow is termed electro-osmotic flow. Electro-osmosis can only occur if there are charged species in the fluid that can respond to the electric field (Jagannadh and Muralidhara 1996).

Electro-osmosis can be described mathematically using the momentum transport equation, as the resulting body force due to an electric field on a charged fluid (Hu and Li 2007). The net charge density of the fluid (ρ_e) can be related to the

electric potential (ϕ) and the permittivity of the fluid (ϵ) by Poisson's equation:

$$\epsilon \nabla^2 \phi = -\rho_e \quad (1)$$

Under negligible convective or electrophoretic-induced flow, the charge density follows a Boltzmann distribution (Hunter 1981), and the charge density can be obtained by solving the nonlinear Poisson–Boltzmann equation:

$$\nabla^2 \phi - \kappa^2 \sinh(\phi) = 0 \quad (2)$$

where the constant κ depends on the ionic composition (Russel et al. 1989). Although solutions to Eq. 2 can only be obtained numerically for complex geometries, it can be linearized using the Debye–Hückel approximation, which leads to the following electric potential distribution:

$$\phi = \zeta \exp\left(\frac{-y}{\lambda_D}\right) \quad (3)$$

where y is the distance from the surface, and $\lambda_D = 1/\kappa$ is the Debye length.

In membrane systems, electro-osmosis can be approximated through the Helmholtz–Smoluchowski (HS) velocity equation:

$$u_s = -\frac{\epsilon \zeta E_x}{\mu} \quad (4)$$

The HS approximation described by Eq. 4 is an artificial slip velocity implemented on a charged

surface. It can be used to simulate the effect of electro-osmosis on the velocity in a conduit at the outer edge of the EDL (Probstein 2005). This equation implies that the electro-osmotic flow velocity is proportional to the applied electric field. Other equations that are relevant to electro-osmosis under different conditions include the Hückel–Onsager equation and the Henry equation.

Most common applications of electro-osmosis are in capillary electrophoresis, capillary electrochromatography, and microfluidic devices in fields as diverse as biophysics, dewatering, geomechanics, medicine, microchips, oil and gas production, and separations including in membrane separation. There are a number of important applications in membrane technology. At the fundamental level, electro-osmosis can be used to determine the zeta potential of membranes (Bowen and Clark 1984). It can also be beneficial for the operation of membrane separation systems, and has found numerous applications in microfiltration and ultrafiltration processes (Bowen 1993), in particular to do with the mitigation of membrane fouling. This is because surface activity and membrane charge, two phenomena closely related to membrane fouling, cannot be influenced through hydrodynamic forces such as increased shear. Electro-osmosis can be used for membrane cleaning and restoration (Bowen et al. 1989), for backwashing (Bowen and Sabuni 1994), for releasing filter cakes in dead-end membrane processes (Bowen and Ahmad 1997), and for enhancing flux (Sarkar and De 2010).

Although the use of DC electric fields in membrane separation processes has been in practice for several decades, anode corrosion is a significant problem that has discouraged its wider application (Jagannadh and Muralidhara 1996). Nevertheless, the development and availability of corrosion-resistant materials has enabled recent developments and commercialization of these techniques. Electro-osmosis has also found applications in RO processes, leading to improved recovery through membrane backwashing (Spiegler and Macleish 1981) or by increasing the level of mixing in the boundary layer (Liang et al. 2014).

Synonyms

Electroosmotic drag flux; Electroosmotic water transport; EOD

Electroosmotic drag in membranes refers to the movement of water or other electroneutral solvents through a membrane, associated with the movement of ions under the influence of an electric field.

The zeta potential at the interface between a membrane and an electrolyte generally leads to the creation of an electric double layer (EDL). When an electric field is applied to fluid within an EDL, the net charge is induced to move by the resulting Coulomb force. The movement of ions drags bound solvent, causing bulk fluid motion

due to momentum transfer (viscous drag). This bulk fluid motion due to an external electric field is termed electroosmosis (De Groot 1966) and can occur in any fluid with a net charge, including in membrane channels or within membrane pores (Fig. 1).

Electroosmotic drag (EOD) is the underlying mechanism responsible for solvent transport in a number of membrane techniques including:

- EOD in electrodialysis (ED), often called “water transport,” is one of the reasons for losing current density (Indusekhar and Krishnaswamy 1965). ED has many industrial applications including the production of chlorine, NaOH, and other inorganic acids and bases (de Groot et al. 2011).
- EOD of water in proton exchange membranes (PEMs, also referred to as polymer electrolyte membranes), which leads to water management issues (Zawodzinski et al. 1995).
- EOD of methanol in direct methanol fuel cells (DMFCs), leading to methanol crossover (Heinzel and Barragán 1999).
- In vanadium redox batteries (VRBs), EOD can cause vanadium crossover and capacity loss (Agar et al. 2013).
- EOD in electroosmotic pumps (EOPs) is used to generate flow or pressure (Wang et al. 2006). EOPs can be used to aid with the hydration of PEMs for fuel cells.
- EOD is a mechanism for producing anomalous flux through charged membranes (e.g., NF membranes) due to the selective

Electroosmotic Drag in Membranes,

Fig. 1 Schematic representation of electroosmotic drag in a membrane pore. The electric field causes the dissolved ions to experience a net force, and these ions transfer momentum to the solvent molecules through viscous drag

passage of one type of charged ion over the other, leading to the axial rearrangement of the EDLs (Sasidhar and Ruckenstein 1982).

EOD is of particular importance in PEMs such as Nafion[®] and sulfonated polyetherketones, used in fuel cells and VRBs. Water management critically impacts the performance of PEMs for fuel cells, as their proton conductivity increases with hydration. Too little water can dry the membrane, leading to a reduction in conductivity and consequently lower cell performance. Too much water can flood the membrane and lead to cathode flooding problems. In addition to the generation of water at the cathode catalyst layer due to the electrochemical reaction, water is also transported through the membrane (Lee et al. 2008). The permeate flux of water in a PEM is governed by two main mechanisms: (a) the osmotic flux due to a chemical potential gradient across the membrane, which is influenced by both the activity of the solution (osmotic pressure) and the hydrostatic pressure, and (b) the electroosmotic flux due to the drag induced by the proton flux (Ren and Gottesfeld 2001).

In order to optimize water concentration in a fuel cell membrane, it is important to quantify electroosmotic drag. The electroosmotic water flux can be related to the proton flux through the membrane by means of the electroosmotic drag coefficient (ps_{drag}), which is defined as the number of water molecules transported through the membrane per proton as the chemical potential gradient of water tends to zero (Ise et al. 1999).

Electrooxidation

Marc Cretin

Institut Européen des Membranes, ENSCM-UM-CNRS (UMR 5635), Université de Montpellier, Montpellier Cedex 5, France

National School of Chemistry of Montpellier, University of Montpellier, Montpellier, France

Electrooxidation is a direct anodic oxidation technique to remove biorefractory pollutants by direct electrolysis in which pollutants exchange electrons with the anode surface without intermediate substances. It differs from indirect anodic oxidation. Indeed by indirect anodic oxidation, pollutants are oxidized by $\cdot\text{OH}$ s radicals generated by water oxidation on a high O_2 evolution anode such as boron-doped diamond (BDD).

Direct anodic oxidation is possible using noble metals (Pt and Pd), metal oxide (IrO_2 , PbO_2), or carbon-based (boron-doped diamond) anodes, before oxygen evolution. The first stage is the pollutant adsorption on the anode surface. The second stage is the oxygen (as a source of electrons) transfer from water to the organic pollutant using electric energy (i.e., anodic polarization) through the so-called electrochemical oxygen transfer reaction (EOTR). A typical example of EOTR often cited in the literature (Panizza and Cerisola 2009) to illustrate direct electrooxidation is anodic incineration of phenol as follows:

The complete phenol oxidation to CO_2 (i.e., mineralization) is obtained at the anode, and protons liberated in this reaction are reduced at the cathode to hydrogen. The pollutant mineralization rate depends mainly on the nature of the anodic material, the choice of the anodic potential (fixed before oxygen evolution), and chemical and physical parameters such as electrolyte and pollutant composition and concentration and temperature.

The main limitation of electrooxidation is the decrease of the electrocatalytic activity of the electrode because of the fast formation of a polymer layer from oxidation intermediates on the anode surface. Film formation depends on the adsorption properties of the electrode surface, the concentration and the nature of organic compounds, their degradation intermediates, the presence of oxygen, etc. Then electrodes presenting a surface with weak adsorption properties are promoted to gain in stability (Panizza and Cerisola 2003). Nevertheless, in anaerobic conditions, the formation of the polymer fouling layer remains the limiting factor of the mineralization.

To overcome this poisoning effect, anode must be polarized over oxygen evolution to promote water discharge, leading to hydroxyl radical ($\cdot\text{OH}$) formation on specific electrode like boron-doped diamond. The electrochemical formation of this powerful oxidant avoids then polymer fouling layer formation and then the decrease of the electrocatalytic activity of the electrode. More details can be found concerning this electrochemical advanced oxidation process (EAOP) in the entry “indirect anodic oxidation.”

Electrophoresis

Catherine Charcosset

Université Lyon 1, Lyon, Villeurbanne, France

The term electrophoresis refers to the motion of suspended particles in an applied electric field. Among separation techniques, electrophoresis is

widely used in research and development and quality control in disciplines such as biochemistry, immunology, genetics, and molecular biology (Westermeyer 2001). Electrophoresis is based on the differential migration of charged species in a semiconductive medium under the influence of an electric field. Separation of many different kinds of species including proteins, DNA, nucleotides, drugs, and many other biochemicals is obtained upon differences in size, charge, and hydrophobicity. The technique was first reported in 1937 by Arne Tiselius who won the Nobel Prize in Chemistry in 1948 for the separation of different serum proteins by a method called “moving-boundary electrophoresis.” Since then, a number of improved techniques have been introduced such as gel electrophoresis, capillary electrophoresis, and two-dimensional electrophoresis.

Gel electrophoresis uses an electric current passed through an agarose or polyacrylamide gel (SDS-PAGE) to separate the molecules in a sample on the basis of their differences in molecular size and charge. As the sample migrates in the gel in response to the electric current, the smaller species move more quickly than the larger species, which results in a distinct banded pattern in the gel. This banded pattern may be visualized via the application of staining agents, such as ethidium bromide, which reveals the gel bands under UV light, or silver stain, which is typically used to detect proteins. The silver stain is compatible with mass spectrometry techniques for further analysis of the protein composition. Capillary electrophoresis (CE) involves a combination of both polyacrylamide gel electrophoresis (SDS-PAGE) and high-performance liquid chromatography (HPLC) (Ahuja and Jimidar 2008). High voltages of 500 V/cm or greater are generated within narrow capillaries (20–200 μm). The high voltages cause electroosmotic and electrophoretic movement of buffer solutions and ions, respectively, within the capillary. Two-dimensional gel electrophoresis (2-D electrophoresis) separates species in two steps, according to two independent properties. In a common technique, the first dimension is isoelectric focusing, which separates proteins according to their isoelectric points; the second dimension is SDS polyacrylamide gel electrophoresis

(SDS-PAGE), which separates proteins according to their molecular size. The method involves placing the sample in gel with a pH gradient and applying a potential difference across it.

Cellulose acetate membranes are other current supporting media for electrophoresis separation (Westermeyer 2001). They are used for routine clinical analysis and related applications, as well as for the analysis of molecules in physiological fluids. These membranes have large pores and therefore have a low sieving effect on molecules. The electrophoretic separation is thus entirely based on charge density. The matrix exerts little effect on diffusion so that the separated zones are relatively wide and the resolution and limit of detection area is low. For these reasons, cellulose acetate membranes are often replaced by gel electrophoresis.

Other supporting membranes for electrophoresis include Nafion membranes, a type of perfluorosulfonic acid membrane, and cation-exchange membranes, which are chemically resistant and consist of a pore-structure cluster network (Fang et al. 2004). These membranes are widely used in the field of chloralkali industry and in fuel cells. A Nafion membrane contains hydrophilic pores (10–20 Å and 50–60 Å in size) acting as very narrow electrophoresis channels. The fixed-charge sites ($-\text{SO}_3^-$) on the hydrophilic pore surface provide a strong charged background. Nafion membrane electrophoresis is a potentially attractive technique for the separation of small organic molecules like amino acids or ions.

Electrophoretic Deposition

Catherine Charcosset

Université Lyon 1, Lyon, Villeurbanne, France

Electrophoretic deposition (EPD), also called electrocoating, e-coating, cathodic electrodeposition, or electrophoretic coating, is a simple and effective technique for coating of charged particles on substrates (Besra and Liu 2007). It has several advantages including continuous processing, uniform deposition and control of the thickness, and morphology of a deposited film by adjustment of the deposition time and applied potential. In EPD, charged powder particles, dispersed or suspended in a liquid medium, are attracted and deposited onto a conductive substrate of opposite charge on application of a DC electric field. There are two types of electrophoretic deposition (Fig. 1). When the particles are positively charged, the deposition happens on the negative electrode (cathode) and the process is termed cathodic electrophoretic deposition. The deposition of negatively charged particles on positive electrode (anode) is called anodic electrophoretic deposition. By suitable modification of the surface charge on the particles, any of the two modes of deposition is possible. This technique is convenient for stable suspensions containing charged particles free to move when an electric field is applied. Therefore, EPD can be applied to any material that is available as a fine powder (e.g., $<30\ \mu\text{m}$ particle size) or as a colloidal

suspension, including metals, polymers, ceramics, and glasses.

The fundamental mechanisms of EPD are described in the literature mainly in the framework of the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory and in relation to the distortion of the particle double layer under the application of a DC electric field (Corni et al. 2008). However, numerous other theories (flocculation by particle accumulation, particle charge neutralization, electrochemical particle coagulation, electrical double layer distortion, and thinning mechanism) have been proposed to explain the particle interactions and the kinetics of deposition.

Several examples of membrane preparation using an EPD technique are reported. For example, EPD is used as a seeding method for making zeolite membranes (Abdollahi et al. 2007). Zeolites are crystalline structures which possess uniform and molecular-sized pores. Zeolite membranes have a great potential in separation and catalysis processes owing to their unique pore structures and adsorption properties and their high thermal, mechanical, and chemical stability compared with polymeric membranes. Since zeolites are negatively charged particles, they can be effectively attracted to the substrates of positive charge. By the aid of EPD, an oriented continuous layer of nano-sized zeolite seeds is formed on the support and acts as nuclei for the next step which is crystal growth under hydrothermal situation.

The EPD technique is also used for the preparation of membrane electrode assembly for fuel cell (Morikawa et al. 2004). A membrane

Electrophoretic Deposition,

Fig. 1 Schematic of electrophoretic deposition process. (a) Cathodic EPD and (b) anodic EPD

electrode assembly can be prepared by EPD process onto a Nafion membrane. A suspension consisting of ethanol, carbon powders with Pt catalyst, and Nafion polymer is used to obtain a stable dispersed solution. The thickness of the prepared catalyst layer is controlled by EPD duration or concentration of suspension. The cell obtained may present a higher electrochemical performance compared with ordinary cells.

Electrophoretic Mobility

Catherine Charcosset

Université Lyon 1, Lyon, Villeurbanne, France

When an electric field is applied across a given medium, charged solutes or particles suspended in the electrolyte are attracted toward the electrode of opposite charge. Viscous forces acting on the component tend to oppose this movement. When equilibrium is reached between these two opposing forces, the solutes or particles move with constant velocity. The velocity is dependent on

factors such as the strength of electric field or voltage gradient, the dielectric constant of the medium, the viscosity of the medium, and the zeta potential of the particles.

The electrophoretic mobility, μ (m^2/Vs), is the observed electrophoretic velocity, v (m/s), divided by electric field strength, E (V/m):

$$\mu = \frac{v}{E}$$

The electrophoretic velocity is the distance of migration divided by time, also called velocity of migration. Mobilities are sometimes expressed with a negative sign, because migration of the solutes or particles generally occurs in the direction opposite to the electrophoretic field (which is taken as reference).

The electrophoretic mobility of charged solutes, including proteins, is predicted using the Debye-Hückel-Henry theory (O'Connor et al. 1996). This theory is valid only for spherical nonconducting particles at low zeta potentials, with ions present in the electrical double layer behaving as point charges. The Debye-Hückel-Henry theory gives the mobility as

$$\mu = \frac{ze}{6\pi\eta r} \frac{f(\kappa r)}{(1 + \kappa r)}$$

where z is the net charge (dimensionless), e the elementary charge (C), r the particle radius (m), η the viscosity ($\text{kg m}^{-1} \text{s}^{-1}$), and $f(\kappa r)$ is the Henry correction factor, which has values between 1 and 1.5. The Debye-Hückel parameter, κ , is defined by

$$\kappa^2 = \frac{2e^2 N_A I}{\epsilon k T}$$

where N_A is the Avogadro's constant (kmol^{-1}), I is the ionic strength (kmol m^{-3}), ϵ is the permittivity ($\text{J}^{-1} \text{C}^2 \text{m}^{-1}$), k is the Boltzmann's constant (J K^{-1}), and T is the temperature. O'Brien and White (1978) obtained a more rigorous solution to the equations describing the electrophoretic mobility of a rigid spherical particle with a uniform charge density. The predictions of this model

coincide with those of the Debye-Hückel-Henry theory for systems with zeta potentials less than 25 mV.

The electrophoretic mobility of proteins has been determined through several microfiltration membranes under conditions of zero concentration driving force and with negligible adsorption on to the membranes occurring during the experiment (O'Connor et al. 1996). The initial mobility of both proteins is close to free-solution values at the same pH, after correction for the ionic strength of the buffer. This effect is explained by the effect of reduced free area in the membrane which is compensated by a corresponding increase in the potential gradient. Data were also obtained for mixtures of two proteins. Interactions occur when the two proteins are oppositely charged, changing the apparent mobilities from the free solution values.

Electrophoretic Painting

Catherine Charcosset
Université Lyon 1, Lyon, Villeurbanne, France

Electrophoretic painting, also called electrophoretic deposition of paint, electrodeposition painting, or E-coating, is an economical and corrosion-resistant technique for applying coatings to electrically conducting materials. It is widely used to

coat many industrial products such as automobile bodies and parts, tractors and heavy equipment, metal furniture, and beverage containers. The process is carried out with the use of anodes and cathodes in the painting tank. There are two types of electrophoretic painting: anaphoretic and cataphoretic painting. In anaphoretic painting the profiles will be the anode, and in cataphoretic painting the profiles will be the cathode. In the electrophoretic painting process, evolution of oxygen gas will take place at the anode, and hydrogen gas will be evolved at the cathode.

The electrophoretic paint is continuously circulated to avoid settling of the paint solids and heat resulting from the pumping process as well as from the passage of electric current. Dry coating thicknesses of the order of 20 μm are normally applied, using a voltage of 150–200 V for a time of 1–2 min. After painting, the profiles are rinsed before stowing at temperatures of 180–200 °C for 20–30 min. The electrophoretic paint may contain a water-soluble acrylic-based paint, the resin being rendered soluble by the addition of suitable amines such as melamine. When current is passed through the paint, the resin and pigments will migrate to the anode while the amine will be discharged at the cathode. During paint deposition the level of amine will increase, and this causes a decrease in paint deposition rate if allowed to continue. The most usual processes used for removal of excess amine are ultrafiltration often in combination with reverse osmosis.

After electrophoretic painting, ultrafiltration continuously treats the paint bath to produce permeate needed for rinsing metal parts (Agana et al. 2011). While permeate is used for rinsing, the mixture of paint and rinse water is returned to the paint bath from the downstream rinse system. The volume in the paint bath remains constant, and the process leads to a closed loop cycle including a multistage rinse system. No wastewater is produced and almost no deionized water is required for the purpose of rinsing. Different types of membranes are available for various types of paint. The type and size of the membrane modules are related to the needs of bath volume and characteristic parameters of the paint bath, such as total solids, pH, and temperature.

Electrospun Nanofiber Membrane for Biosensors

Michele Modesti, Carlo Boaretti and Martina Roso

Department of Industrial Engineering, University of Padova, Padova, Italy

A biosensor is an analytical device comprising three main elements: a biological recognition element able to interact specifically with a target, a transducer able to convert a change in property of the solution or surface into a recordable signal, and a processing system which is able to amplify and quantify the signal. The involved biomolecular interactions in the bio-receptor/analyte complex can be based on antibody-antigen interactions, enzymatic interactions, nucleic acid interactions, and cellular or analyte/synthetic receptor interactions.

Biosensors are generally classified according to transduction modes and recognition elements (D'Orazio 2003; Rodriguez-Mozaz et al. 2004) in five principal transducer classes that are electrochemical, optical, thermometric, piezoelectric, and magnetic. Moreover, electrochemical sensors may be subdivided into potentiometric, amperometric, or conductometric types (Thevenot et al. 2001). Biosensors represent nowadays the answer to a pressing need of advanced solutions for sensitive detection of the physiological chemicals involved in clinical diagnosis.

Within this scenario, electrospinning is an economic and versatile technology for producing one-dimensional nanomaterials that possess high specific surface area and high porosity. In this technology, an electrified jet of polymer solution is obtained by applying a relatively high electric tension. If the viscoelastic forces on the polymer solution are sufficient to contrast jet breaking, a nonwoven web of fibers ranging from few nanometers to several microns is collected on a proper support. Several reviews and books about electrospinning (Bhardwaj and Kundu 2010; Ramakrishna et al. 2005; Wendorff et al. 2012) are available for having a better understanding of this technique. The majority of electrospun fibers are polymer-based or polymer-inorganic composites. It has been shown they have a good biocompatibility and consequently they represent a good candidate for biosensor fabrication especially as a matrix for protein or enzyme immobilization (Li et al. 2014).

Among biosensors, monitoring changes in extracellular glucose concentration is one of the most important ones because it is related to both brain disease and neurological disorders, and it is also the key analyte for medical diagnostics and management of diabetes. A complete and exhaustive review on glucose biosensor and all the basic principles of them can be found in the scientific literature (Yoo and Lee 2010). The most common glucose biosensors achieve specific recognition of glucose by immobilization of the enzyme glucose oxidase (GOD) on the surface of electrodes Wu and Fan (2013). The basic concept of the glucose biosensor is based on the fact that the immobilized GOD catalyzes the oxidation of β -D-glucose by molecular oxygen, producing gluconic acid and hydrogen peroxide. Three general strategies are used for the electrochemical sensing of glucose: by measuring oxygen consumption, by measuring the amount of hydrogen peroxide produced by the enzyme reaction, or by using a diffusible or immobilized mediator to transfer the electrons from the GOD to the electrode (Yoo and Lee 2010). At this regard, polyvinyl alcohol (PVA) nanofibers have been shown to be useful in producing an amperometric glucose biosensor (Ren et al. 2006) which exhibited a rapid response time

(1 s) and a higher output current (μA level) to glucose in the normal and diabetic level. The linear concentration response range from 1 to 10 mM and the lower detection limit (0.05 mM) of the sensor can meet the demand in the detection of the glucose in medical diagnosis.

In enzyme-based biosensors, the sensitivity and longevity of the biorecognition element are functions of the physical design and the enzyme stability over time (Wilson and Gifford 2005). Moreover, temperature, pH, and other chemicals can easily affect the activity and stability of the immobilized enzyme as well as the immobilization chemistry and the microenvironment of the enzyme on the electrode (Marx et al. 2011).

In order to get an efficient enzyme encapsulation and the absence of interference from other coexisting electroactive species, the biocomposite based on Prussian blue, chitosan, and polyvinyl alcohol has been fabricated by electrodeposition and subsequent electrospinning in enzyme-friendly conditions. Prussian blue (PB), known as “artificial peroxidase,” has been employed in fabricating amperometric glucose biosensors because of its well-known capabilities for enhancing electron transport and excellent catalytic activity toward H_2O_2 reduction at a low overpotential. The modified electrode has been shown to exhibit such a rapid direct electron transfer rate that the glucose sensor exhibited excellent performance, which includes wider linearity, lower detection limit, and good stability in optimized conditions (Wu and Yin 2013).

Another way for improving sensitivity and lifetime of the immobilized enzyme is the application of conducting polymers to bioelectronic surfaces; the advantage of using such electrospun polymers is related to their ability to increase the signal-to-noise ratio (S/N), and, at the same time, they are a suitable matrix for the immobilization and entrapment of enzymes (Yang et al. 2014). For instance, Yang et al. compared the performance of enzyme-entrapped conducting polymer nanofibers (NFs) with reference to its conducting polymer film (F) counterpart. Among different conducting polymers, poly(3,4-ethylenedioxythiophene) (PEDOT) has been chosen as support for GOD enzyme because of its

chemical stability and good electrical conductivity. Poly(L-lactide) (PLLA) has been electrospun on Pt microelectrodes followed by the electrochemical deposition of PEDOT-GOD on the Pt microelectrodes and around PLLA nanofibers. Comparing the performance of the two different nanostructured sensors (PEDOT-F vs. PEDOT-NFs), it has been shown that the increase of surface area related to the nanofibers affects both the impedance of the biosensor (which is sensitively lower) (Abidian et al. 2010) and it allows more GOD to be entrapped on the biosensor. Both of these results contribute to the increased sensitivity of the PEDOT-NFs-GOD biosensors.

Nevertheless, the scientific research on biosensors is moving also toward the design and development of nonenzymatic glucose sensors based on direct oxidation of glucose at modified electrode surface (Kong et al. 2012). According to Ding et al. (2010), metals (Au, Pt, Ni, Cu) and metal oxides (ZnO , CuO , etc.) have been exploited to construct a variety of enzyme-free glucose sensors. Among the aforementioned metal oxides, cobalt oxide nanofibers (Ding et al. 2010) have been obtained by electrospinning and subsequent calcination, and they have been used for glucose detection in an alkaline medium. The developed sensor has been shown to have a fast response time (less than 7 s), a high sensitivity of $36.25 \mu\text{A mM}^{-1}\text{cm}^{-2}$, good reproducibility and selectivity, and a detection limit of $0.97 \mu\text{M}$ ($\text{S/N} = 3$). The high sensitivity and low detection limit has been hypothesized to be related to the excellent catalytic property of the as-prepared Co_3O_4 nanofibers and to their highly porous 3D network. The latter provides high specific surface area and numerous active sites, and it allows the access of analytes to the active catalytic sites with minimal diffusion resistance. Another attempt to get nonenzymatic glucose sensor has been reported in the research of Cao et al. (2011), wherein nickel oxide microfibers (NiO-MFs) have been directly immobilized onto the surface of fluorine tin oxide (FTO) electrode by electrospinning followed by calcination without using any immobilization matrix. The amperometric performance of glucose at

NiO-MFs-modified electrode have shown an ultrasensitive current ($1785.41 \mu\text{A mM}^{-1} \text{cm}^{-2}$) response and low detection limit of $3.3 \times 10^{-8} \text{M}$ ($\text{S/N} = 3$).

Despite the presence of enzyme-based and nonenzyme-based biosensors, there are also other support-enzyme hybrid substrate materials for biosensors. An example that has been investigated by researchers was based on water-stable PVA and PVA/poly(ethyleneimine) (PEI) nanofibers decorated with silver nanoparticles (AgNPs) (Zhu et al. 2013). By combining an in situ reduction approach and electrospinning technique, a H_2O_2 , glutathione (GSH), and glucose detection biosensor has been obtained, showing a high sensitive detection of H_2O_2 with a detection limit of $5 \mu\text{M}$ and a fast response, broad linear range, low detection limit, and excellent stability and reusability.

Looking at the aforementioned literature, it appears evident that the ongoing trend in biosensor fabrication is the use of specific nanomaterials to get better sensitivity, lower detection limit, and linear response range. Further evidence of this is the H_2O_2 -modified electrode based on hemoglobin (Hb) collagen and carbon nanotubes (CNTs) proposed by Li et al. (2014). Hb has been used because of its similar structure to peroxidase, CNTs for the electrical properties, and collagen for its excellent biocompatibility. Therefore, the resulting hemoglobin-collagen-carbon nanotube (Hb-collagen-CNT) composite nanofiber-modified electrode has excellent performance, thanks to the great surface area and the high porosity of the three-dimensional reticular structure which ensures more channels for both electron transfer and diffusion of H_2O_2 .

Among enzymes currently used in biosensor fabrication, urease (Sawicka et al. 2005), fructose dehydrogenase (Marx et al. 2011), α -chymotrypsin (a proteolytic enzyme acting in the digestive systems of many organisms) (Jia et al. 2002), and lipase (Li et al. 2007; Ye et al. 2006) represent just a few examples of the ongoing research. The large surface area of electrospun nanofibers has been found to be important for increasing both the amount of immobilized enzymes and their own catalyzing

activity, thanks to an effective reduction of the diffusion resistance of the substrates/products.

Further challenge in detecting DNA repair represents a key factor in cancer diagnostic. Due to the subtlety of DNA damage, it is difficult to sense the presence of damaged repair with high selectivity and sensitivity. In this regard immobilizing DNA on gold/polymeric electrospun nanofibers and their use in electrochemical sensing of DNA repair processes have been shown to be very promising, showing the potential of these low-cost devices for sensing applications (McWilliams et al. 2014). Polyacrylonitrile electrospun fibers coated with gold nanoparticles have been tested and thiolated DNA has been assembled on these fibers. It has been demonstrated that the fibers themselves become the working electrode of the sensors, modified with either the lesion-bearing or defect-free DNA monolayers. From the reported assays, the device sensitivity has been found to be on the order of femtomoles per electrode, and it means that sensing can be accomplished with even 1 ng of enzyme.

Electrospun Nanofibers for Water and Wastewater Treatment Applications

Michele Modesti, Carlo Boaretti and Martina Roso

Department of Industrial Engineering, University of Padova, Padova, Italy

E

Water pollution is the contamination of water bodies (e.g., lakes, rivers, oceans, aquifers, and groundwater), and it occurs when pollutants are discharged directly or indirectly into water bodies without adequate treatment to remove harmful compounds. Direct sources include effluent outfalls from factories, refineries, waste treatment plants, etc., that emit fluids of varying quality directly into urban water supplies. Indirect sources include contaminants that enter the water supply from soils/groundwater systems and from the atmosphere via rainwater. Soils and groundwaters contain the residue of human agricultural practices (fertilizers, pesticides, etc.) and improperly disposed of industrial wastes. Atmospheric contaminants are also derived from human practices (such as gaseous emissions from automobiles, factories, and even bakeries). Contaminants can be broadly classified into organic, inorganic, radioactive, and acid/base. Moreover, bacteria and virus represent a dangerous class of contaminating agents, which are responsible of diseases in developing countries.

Microbial Control of Water

Currently the basic water treatments for microbial control require chemical disinfectants and membrane-based filtration systems. If the formation of harmful disinfection by-products from chemical disinfectants is the potential drawback that makes their use not completely reliable (Li et al. 2008), water filtration membrane is affected by biofouling and virus penetration. Biofouling can be considered as a biotic form of

organic fouling, and it represents a major problem in nanofiltration (NF) and reverse osmosis (RO) membrane filtration.

At this regard, electrospun nanofibers have been found to be a good candidate for improving the performance of filtering media. Antifouling properties can be achieved by plasma treatment or surface graft polymerization of nanofibers, as suggested by the literature (Musale and Kumar 2000). Another advantage related to the use of electrospun nanofibers for microbial control is the capability to get a wide range of assemblies, for instance, antimicrobial nanofibers themselves and nanobiocides, which include metal, metal-oxide nanoparticles, engineered nanomaterials (fullerenes and carbon nanotubes), and natural substances (Botes and Cloete 2010). For instance, nanoparticles of Ag, TiO₂, and ZnO represent low-cost materials with a well-known antimicrobial activity that can be properly attached to nanofibers reducing potential toxicity and leaching effects.

Polyurethane, poly(vinylidene) fluoride-co-hexafluoro-propylene (PVDF-HFP), and polycarbonate with quaternary ammonium salt are just few examples of antimicrobial nanofilters which have been shown to have a very good filtration efficiency of 0.3 mm size particles (99.93 %) and a very strong antimicrobial activities against both *S. aureus* and *E. coli* (Yao et al. 2008, 2009; Kim et al. 2007).

Desalination

Another challenging task related to the water issue regards the need of alternative sources in order to tackle the higher demand for fresh water and energy resources. Desalination technology that converts seawater into clean water has been found to be a suitable approach for it. Among the different membrane separation processes, membrane distillation (MD), electrodialysis (ED), reverse osmosis (RO), freeze desalination (FD), ion exchange (IX), and nanofiltration (NF) have been developed as desalination technologies (Sundarrajan and Ramakrishna 2013).

Nanofiltration is a type of pressure-driven membrane process with properties in between reverse osmosis (RO) and ultrafiltration (UF), which has been found to be adequate for desalination with low salt content. According to the established technology, in order to reduce the resistance and enhance the flux, thin film composite membranes (TFC) are commonly used. They are based on three layer, that is, a nonwoven fabric as support, a middle porous support, and a top layer which is responsible for the selective salt removal. Within this scenario, electrospun nanofibers can be used as a mid-layer membrane in order to achieve higher flux and low fouling behavior than the commercial NF membranes (Yung et al. 2010). Nevertheless, the applicability of electrospun membranes as self-supporting NF membranes has been proved (Kaur et al. 2012) even though a careful optimization of the whole system needs further studies in terms of process optimization and cost analysis.

As regards desalination by membrane distillation (MD), nanofibrous membranes based on electrospun polymers (polyvinylidene fluoride, PVDF) and copolymers (PVDF-co-F6PP, PVDF-co-hexafluoropropene) have been proven to reduce the energy requirements of direct contact membrane distillation process, thanks to the higher permeate flows (Khayat et al. 2011; Shih 2011) than PTFE commercial membranes. Very good performance in a direct contact membrane distillation setup could be achieved also by self-supporting carbon nanotube (CNT) membranes (Dumée et al. 2011), which have to be properly modified for enhancing their hydrophobicity and that allow to get a 99 % salt rejection and a flux rate of 12 kg/m².

Heavy Metal Ions Removal

Water pollution by heavy metal ions is another important related issue because long-term exposure to metal ions such as lead (Pb) can result in acute or chronic damage to the brain and the central nervous system on humans. Furthermore, heavy metals are dangerous because they tend to

bioaccumulate, i.e., the concentration of a chemical increases in a biological organism over time, compared to the chemical's concentration in the environment (Lee et al. 2013). Among the technologies employed for the treatment of contaminated water (chemical oxidation, precipitation, IE, RO), adsorption and membrane separation could be enhanced by electrospun nanofibers. In the literature several examples are reported, the central ideas of which are:

- i. The functionalization of the fibers with such molecules able to bind metal ions
- ii. The surface modification of polymer in order to vary certain properties, such as hydrophilicity or hydrophobicity, water absorbency, adsorption capacity, and resistance to microbial attack
- iii. The production of mixed nanocomposite fibers

As regards the functionalization of fibers (point i), rhodanine is a heterocyclic molecule that belongs to the sulfur-containing N and O organic compounds which possesses uptake performance toward Ag (I), Pb (II), and Hg (II) ions (Lee et al. 2013). On the other hand cellulose and chitosan-/polyacrylamide-modified nanofibers have been proven to be suitable for the adsorption of trace of metals (Cd, Pb, Cu, Cr, and Ni) from the river water and treated water (Musyoka et al. 2013). Their adsorption capacity has been enhanced (point ii) by surface modification using furan-2,5-dione. The electrospun iron oxide–alumina fiber systems represent an example of nanocomposite fibers (point iii) that have been used as adsorbent for the removal of heavy metal ions, i.e., Cu^{2+} , Ni^{2+} , Pb^{2+} , and Hg^{2+} from aqueous system (Mahapatra et al. 2013).

Electrospun Nanofibrous Membranes

Martina Roso, Carlo Boaretti, Alessandra

Lorenzetti and Michele Modesti

Department of Industrial Engineering, University of Padova, Padova, Italy

Introduction

Nanofibers are an interesting and versatile class of one-dimensional (1-D) nanomaterials, with diameters ranging from tenths to hundreds of nanometers, which have been recognized as promising due to their outstanding properties in terms of high porosity, excellent pore interconnectivity, small diameters, and high surface-to-volume ratio. Among the different nanofiber manufacturing technologies, electrostatic spinning or *electrospinning* represents the easiest, most promising, and versatile method for the generation of aligned or randomly distributed nanofibers of a rich variety of different materials like synthetic and natural polymers (Huang et al. 2003), composites (Sahay et al. 2012), ceramics (Dai et al. 2011), and metals (Wu et al. 2007).

With this technique that is essentially a variation of the electrostatic spray (or *electrospraying*), a fiber is produced thanks to the solidification of an electrified jet of a solution that is stretched by the repulsive action of surface charges and evaporation of solvent. The main difference with respect to *electrospraying* is the presence of high elongational viscous forces generated by the chain entanglements of the polymer present in the solution that, thanks to the application of a strong electric field, prevent the formation of liquid droplets in favor of a rapid whipping jet. The electrospun solution is essentially polymer based, with the possibility to add metal or ceramic precursors that after *electrospinning* treatments can generate the corresponding nanofibers.

An extensive research activity has been carried in the last years toward the evaluation of electrospun nanofibrous membranes (ENMs) in the context of membrane technology, fueled by

the advantages offered in terms of cost and productivity over more complicated bottom-up approaches, flexibility of the membranes, and the potential upscaling for industrial production (Persano et al. 2013).

Fundamentals

The generation of nanofibers by *electrospinning* starts from a solution of a proper solvent in which the desired material is dissolved at a suitable concentration. This solution is usually poured in a syringe or a pipette from which it is let flown through a nozzle using a micropump, and by means of a high-voltage direct current power supply (5–50 kV), an electrostatic field is applied between the nozzle and a metal collector with opposite polarity. By increasing the intensity of the electric field, a charge is induced on the surface of the solution at the tip of the capillary. The mutual repulsion of the charges elongates the hemispherical drop to form a conical shape (*Taylor cone*). Once that the electric field has reached a threshold value, the electrostatic force overcomes the surface tension and a charged jet of solution is ejected from the tip of the Taylor cone, producing a jet that travels toward the metal collector. During this last phase the jet undergoes a whipping process in which it is stretched and the solvent of the solution evaporates leaving a fiber that is collected on a grounded collector.

The morphology and diameter of electrospun nanofibers depend on a wide range of parameters, which can be classified according to three main different categories:

- *Solution parameters*: type of solvent, viscosity, molecular weight and molecular weight distribution, vapor pressure, surface tension, and solution conductivity
- *Process parameters*: solution feeding rate, electric field strength, distance between the tip and the collector, needle diameter, composition, geometry, and motion of the collector
- *Ambient parameters*: temperature, humidity, and air velocity.

Between them viscosity has a prominent role in relation to the morphology of the nanofibers. For polymer solutions of low viscosity, surface tension is the dominant aspect and just beads or beaded nanofibers are obtained. As the viscosity of the solution is increased, the beads become bigger, the average distance between them longer, and the shape of the beads changes from spherical to spindle-like with a decrease of the fiber diameter. At a suitable concentration, smooth nanofibers without defects can be obtained, but with a progressive increment of its value, the fibers increase their diameter until they change their shape into micro-ribbons. Usually the proper viscosity is defined in relation to the specific polymer-solvent system, and for a given polymer-solvent system, it can change according to the molecular weight of the polymer. Complex architectures like core-shell, porous, and hollow structures can be formed by *electrospinning* through the incorporation of nanoparticles into fibers, *co-electrospinning* of different polymers, or employing solutions with different boiling point solvents, while modification of the electrode-collector system allows to orientate the fibers and to obtain 3-D structures (Teo et al. 2011).

Electrospun nanofibers can also be obtained from polymer melts at high temperature, from a combination of a magnetic and electric field, aerated polymer solution, and from multi-jet devices in order to improve production rate.

Applications

The interesting properties related to the possibility of obtaining nanometric fibers from *electrospinning* allow their use for several potential applications, with a multidisciplinary perspective. Broadly speaking it is possible to identify four main areas of interest (Ramakrishna et al. 2005): bioengineering, environmental engineering and biotechnologies, energy and electronics, and, finally, defense and security. In this framework the specific fields of applications in which electrospun nanofibers are directly in contact with membrane technology are several,

including the most traditional and advanced technologies: air and water filtration, fuel cell membranes and battery membrane separators, biomedical applications, and many others. Most of these applications haven't already reached their industrial level, but the promising results from the research field and their different potential applications are believed to encounter the interest of industry and governments. Actually the most industrially developed products based on ENMs are filters for air purification. Potential products ready to market are related to liquid filtration and energy storage, in the short-medium period, and to the biomedical field, in the medium-long period (Persano et al. 2013).

Air and Water Filtration

ENMs' high specific surface, porosity and permeability, tailorable thickness, and fiber diameters are desirable features for filtration applications. These materials have been employed for several years for air filtration and recently, at a research level, even for microfiltration, ultrafiltration, and nanofiltration in the field of water treatment. The advantages of electrospun nanofibers compared to conventional air filter media are related to a higher filtration efficiency, lower pressure drops, and energy savings. Indeed, nanofibers with diameters lower than 0.5 μm have much higher capability to collect fine particles because of the slip flow that increases diffusion, interception, and inertial impaction efficiencies, determining a lower drag force around the fibers and, thus, lower pressure drops. In addition these media are easy to clean, enabling them to significantly extend the life of filters and reducing the maintenance costs. Their potentials have shown possible applications in air filtering media (Barhate and Ramakrishna 2007), especially for high-efficiency particulate and low-penetration air filters, filters for transportation applications, adsorptive catalytic gas filter for respirators, filter media for pulse clean cartridges in dust collection, and cigarette filters for smoke filtration.

ENMs can be employed also for water treatment (Cloete et al. 2013) and generally show high flux rate and low transmembrane pressure with performance comparable to those commercially

available. The main interesting application in this area is related to desalination, VOC gas stripping, oil/water emulsion separation, microbial, organic compounds, and heavy metal removal. However, for solid-liquid filtration, very high surface-to-volume ratios promote membrane fouling. For this reason and for improving membrane performances, ENMs can be surface modified (Nasreen et al. 2013), in order to add functional groups or functionality, with processes like in situ graft and interfacial polymerization, plasma treatment, wet treatment, coating, and blending with surface-modifying agents. A main drawback for the employment of electrospun nanofibers for such applications is their mechanical strength which is not sufficient to withstand macroscopic impact during filtration application such as normal liquid or air flows passing through them. Hence, they need to be used as active coating layer on existing melt-blown supportive fibrous media (composite membrane) or the fibers need to be bonded to enhance mechanical properties.

Fuel Cell and Battery Separator Membranes

Another area in which ENMs can have promising applications is that of energy-related applications and devices (Cavaliere et al. 2011), especially for polymer fuel cell and lithium-ion battery electrolyte membranes.

Research efforts on polymeric proton exchange membranes for fuel cells have led the interest of researchers toward the employment of ENMs as porous reinforcing mats to minimize in-plane swelling and shrinking. Nanofibers are also able to increase proton conductivity with respect to bulk film, thanks to their highly oriented ionic domains (Dong et al. 2010) and provide good mechanical strength, while the remarkable flexibility of their production process allows to adequately tailor their final morphology for composite membranes. Fuel cell membranes are semi-permeable membranes that have the function to be proton conductive, electron insulating, and dense in order to avoid fuel crossover. For this reason two types of approaches can be used when employing *electrospinning* for such application. The first is related to the *electrospinning* of

nonconductive or less conductive polymer into a porous matrix, which acts as mechanical reinforcement when the pores are filled with a highly proton-conductive component. Alternatively, a highly proton-conducting matrix is electrospun into a porous fiber mat and subsequently reinforced with a secondary polymer to provide mechanical stability. The proton-conductive polymers are usually chosen between perfluoro-sulfonic acid and sulfonated polymers that can be coupled with organic or inorganic particles as conductor enhancers or to improve strength and hydrophilicity.

Electrospun mats are also attractive alternatives to polymer gel electrolytes for lithium-ion batteries, since they can be employed as matrix in which the electrolyte can be encapsulated improving ionic conduction across the membrane and mechanical strength while providing good water uptake. In these fields the most widely studied polymer has been poly(vinylidene fluoride) (PVDF) thanks to its good electrochemical and thermal stability. However, PVDF-based gel polymer electrolyte with its high crystallinity limits the ion migration, lowering the battery performance. ENMs with their porous membrane are capable to overcome this problem, and PVDF and other alternative polymers and blend have been explored by *electrospinning* with encouraging results.

Biomedical Applications

Nanofiber research applications in the biomedical field have a multifaceted perspective spreading between tissue engineering, drug delivery, and wound dressing (Agarwal et al. 2008). Tissue engineering is an emerging multidisciplinary area in which nanofibers represent an important advancing front for the production of suitable scaffolds of different materials that can mimic natural extracellular matrix. To this purpose ENMs have been tested as natural, synthetic, and composite scaffolds for different types of targeted tissue including blood vessel, cartilage, bone, nerve, and many others. The small diameter of the fibers and their high surface area are beneficial for cell attachment and bioactive factor loading, enhancing cell growth.

Drug delivery membranes incorporate a drug component that can be patched on wound of surgery or encapsulated into pharmaceutical capsules to deliver the drug through the digestive system of the patient. Polymeric electrospun drug delivery systems are advantageous for such task because they can deliver drugs efficiently to a localized area, with the possibility to vary the release rate by simply varying the fiber diameter or the loading dosage. The possibility of choosing different materials, processes, and processing conditions allows to reach the desired encapsulation efficiency, preserving bioactivity (Zamani et al. 2013). Several drugs have been incorporated successfully into electrospun media obtaining better performance over normal cast film and with the possibility to load insoluble drug for enhancing their dissolution.

ENMs have also exhibited potential in wound dressing thanks to the possibility to generate homogeneous scaffolds, provide uniform adherence, and wet wound surface without fluid accumulation. They can provide high gas permeation and protection from infection and dehydration, extending their applications on different types of wounds as compared to traditional wound dressing materials and opening new doors for the next generation of wound dressing materials.

Other Applications

Electrospun materials from stable polymers or ceramic fibers are also ideal candidates as supports for homogeneous and heterogeneous catalysis in gas phase, since they can provide high surface area and high porosity. The catalyst, which is usually a semiconductor, can be the nanofibrous mat itself, or it can be subsequently added by surface modifications or deposition. Examples are organic or inorganic nanofibers on which metals or semiconductor nanoparticles are deposited or embedded for catalytic (Basheer 2013) and photocatalytic oxidation (Modesti et al. 2014) and synthesis (Formo et al. 2009) of organic compounds in gas phase. The advantages of the high surface areas of the catalytic filters obtainable with this technique are related to higher activity with respect to common porous

catalysts for the abatement of selected compounds.

The characteristics of ENMs match well the requirements for different types of sensing devices (Ding et al. 2009) including acoustic wave, resistive, gravimetric, photoelectric, optical, and amperometric sensors. Indeed, ENMs' high surface area has the potential to provide unusually high sensitivity, fast response time, and lower detecting limits. In this case different approaches can be employed to provide a sensing capability to nanofibers, such as *electrospinning* of a polymeric sensing material, incorporation of sensing molecules into nanofibers, or application of sensing material on nanofiber surface via coating/grafting technique, employing organic and inorganic polymer.

Other potential applications of ENMs include affinity membranes for protein purification (Ma et al. 2005) and protective clothing against nanoparticles (Faccini et al. 2012) on textile support.

Electrospun Polyethersulfone Nanofiber Membranes

Michele Modesti, Carlo Boaretti and
Martina Roso

Department of Industrial Engineering, University
of Padova, Padova, Italy

Electrospun polyethersulfone (PES) nanofiber membranes are semipermeable membranes obtained by *electrospinning* that have been explored for possible applications concerning water filtration (*microfiltration*, *nanofiltration*, and *engineered osmosis*), composite polymer electrolyte membranes, and tissue engineering.

Polyethersulfone (PES) is a high-performance aromatic polymer which belongs to the family of polysulfones. The basic repeating unit of the polymer backbone consists of *para*-linked aromatic groups connected by ether and sulfone groups (see Fig. 1).

PES is synthesized by polycondensation of 4,4-sulfonylbisphenol (bisphenol S) with

Polyethersulfone (PES)

Electrospun Polyethersulfone Nanofiber Membranes, Fig. 1 Repetitive unit of polyethersulfone

4,4'-dichlorophenyl sulfone via nucleophilic substitution at high-reaction temperature (up to 285 °C) in the presence of a suitable solvent like diphenyl sulfone, sulfolane, or N-methyl-2-pyrrolidone (Parker et al. 2012).

PES is a widely employed polymer for membrane fabrication due to its interesting properties in terms of high glass transition temperatures, good mechanical strength and stiffness, and outstanding thermal and oxidative resistance. This polymer can be electrospun from solutions of suitable concentration with polar aprotic solvents (e.g., dimethylacetamide) in order to produce nanofibers with average diameters of 0.75–2 μm and average specific surface area of 15–30 m^2/g , by changing the process parameters (Kwak et al. 2013).

Electrospun nanofibrous membranes (ENMs) are a new class of energy-saving membranes that are under extensive study because of their high interconnected porosity and tunable pore size that can give high permeability and selectivity. One of the most important fields of interest for ENMs is water filtration for which these membranes could overcome some intrinsic limitations of conventional porous polymeric membranes. However ENMs suffer of poor mechanical strength, while PES, even if extensively used for commercial membranes, is a highly hydrophobic polymer so the synthesis of composite membranes is the usual approach to solve these issues. PES ENMs can be employed for dye and heavy metal removal by blending with polymers that incorporate functional groups that have binding/chelating capability (Min et al. 2012; Wu et al. 2014). The mechanical properties of these membranes can be improved by interfiber adhesion/junction (Yoon et al. 2009; Homaeigohar et al. 2012), while the hydrophilicity can be increased by oxidation treatment (Yoon et al. 2009). A combination of both improvements can be achieved by incorporation of hydrophilic inorganic particles which can also allow a higher thermal stability (Homaeigohar et al. 2011). PES ENMs can be employed even as a middle layer in thin film composite polymeric membranes for engineered osmosis with the advantage to provide higher osmotic fluxes than their commercial counterparts (Bui et al. 2011).

Other potential applications concern polymeric scaffolds as substrate for stem cell culture made of pristine (Christopherson et al. 2009; Ardeshirylajimi et al. 2013) and modified (Chua et al. 2006; Shabani 2009) PES, for which both the fiber diameter and the type of functionalization can have a prominent role in the infiltration, differentiation, and proliferation of the cells.

The high stability of the polymer and its chain flexibility due its structure make PES a suitable candidate as non-fluorinated replacement for proton exchange membranes, especially for direct methanol fuel cells. By sulfonation it is possible to introduce proton conducting functional groups along the polymer chain, while by electrospinning a suitable nanofibrous web can be produced. This nonwoven structure can be filled with Nafion to obtain a compact membrane with higher electrochemical performances with respect to Nafion 112 and Nafion 117 dense membranes (Shabani et al. 2010; Hasani-Sadrabadi et al. 2011).

- fertilization and contains from 64 to several hundred cells organized in an outer shell, the trophectoderm, and the inner cell mass (ICM). The ICM is the locus of pluripotent cells destined to yield all the tissues of the developed organism. In the process of obtaining embryonic stem cells, the trophectoderm is removed by immunosurgery, and the ICM is disaggregated and plated on feeder cells. Ethical issues surround the derivation of human ES cells from in vitro fertilized blastocysts.
- Embryonic stem cells have pluripotency and indefinite replication characteristics. These cells have the capacity to give rise to differentiated progeny representative of all three embryonic germ layers (ectoderm, endoderm, and mesoderm). ES cells are able to differentiate in all cell types differently from adult stem cells that can produce only a limited number of cell types. It is possible to modulate the differentiation of stem cells in a given phenotype by using specific growth factors and molecules, which trigger the differentiation process.
- ES cells for their ability of propagating themselves indefinitely represent a valuable tool for both research and regenerative medicine. They can serve as an unlimited source of any cell type in the body; human ES cells could yield highly effective in vitro models for use in drug discovery programs and provide a renewable source of cells for use in transplantation therapy. Cell therapies based on the use of ES cells have been proposed for tissue replacement after injury or disease.
- Adult stem cells, isolatable from bone marrow, adipose tissue, tooth pulp, and many other locations of the body, are capable of self-renewal and can be readily expanded ex vivo for several passages without losing their self-renewal capacity. Mesenchymal stem cells can differentiate into multiple tissue-forming cell lineages such as osteoblasts, chondrocytes, adipocytes, tenocytes, and myocytes. Recent work on the differentiation of bone marrow-derived mesenchymal stem cells into neuron-like cells is another demonstration of considerable plasticity of adult mesenchymal stem cells. Stem cells are often a preferred cell source for regeneration of multiple cell lineage tissues. The ability to expand stem cells is desired to generate cells for tissue engineering in clinical and pharmaceutical applications (Rahaman and

Embryonic Stem (ES) Cell

Loredana De Bartolo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Embryonic stem (ES) cell is a totipotent stem cell derived from an early stage embryo, which is called blastocyst. This stage is reached 4–5 days after

Mao 2005). Conventional methods for expanding stem cells or progenitor cells comprised polystyrene culture dishes and component of extracellular matrix such as collagen. Alternatively biocompatible and biodegradable materials have been proposed to support cells and promote their differentiation and proliferation toward the formation of a tissue (Piscioneri et al. 2011).

Advances in cell-based therapies would not have been possible without the innovative design and fabrication of several generations of biomaterials. Novel biomaterials with distinct properties are necessary to accommodate the growth and interactions of multiple cell lineages in composite tissue constructs (Griffith 2000). Membrane systems provide the temporary structural framework for tissue-forming cells to synthesize extracellular matrices and other functional components in the intended shape and dimensions (De Bartolo and Bader 2013). They can respond on the key demands for utilizing cell-based therapies to engineer composite tissue constructs with a purposeful orientation toward anatomic structures that the tissue-engineered constructs are intended to regenerate. Development of new intelligent biomaterials in synergy with cell biology will advance stem cell-based clinical therapeutics. Engineered membranes have the potential to mimic and control the physical, chemical, and biological factors necessary for guiding stem cell differentiation (Pavlica et al. 2009). They are currently being investigated to act as scaffolds to guide and improve 3D tissue formation, substrates to enhance cell culturing techniques, vehicles for cell delivery, and sources of immobilized and/or time-released factors. They can be applied to the regeneration of numerous tissue types, including the liver, pancreas, bone, cartilage, skin, and nerves, and are being used for the in vitro realization of physiological models.

Emulsification

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Emulsification is a process by which one phase is broken up, dispersed, and distributed in a second immiscible or partially miscible phase (Leal-Calderon et al. 2007). Many different emulsification methods can be identified, and they can be distinguished in nonmechanical and mechanical methods. The nonmechanical methods include the dispersed phase precipitation and the phase inversion. Changes in the phase behavior of the substances to be emulsified, promoted by variation of temperature or composition or by mechanical stress, are used to achieve the desirable state of the system. The mechanical methods of producing emulsions include the use of high-speed mixers, colloid mills, high-pressure valve homogenizers, ultrasonic homogenizers, microfluidization, and membrane emulsification. Depending on the nature of the starting materials, emulsification can be distinguished into two categories. The creation of an emulsion directly from two separate liquids is defined as primary emulsification, whereas the reduction in size of the droplets in preformed emulsion is defined as secondary emulsification (Fig. 1).

The physical processes that occur during emulsification can be highlighted by considering the behavior of two immiscible liquids in a container such as oil and water. Their thermodynamically

Emulsification, Fig. 1 Emulsification

most stable state consists of a layer of oil on top of a layer of water that allows to minimize the contact area between the two phases. To create and emulsion, it is necessary to supply energy in order to disrupt and mix the oil and water which is usually achieved by mechanical agitation. The droplets formed are constantly moving around and frequently collide and coalesce with neighboring droplets. The presence of an emulsifier prevents the merging together of the droplets after they are formed. The emulsifier adsorbs to the surface of the droplets during emulsification and forms a protective membrane that prevents the droplets from coming close enough together to coalesce. The rates of droplet disruption, droplet coalescence, and emulsifier adsorption within a particular homogenizer depend on the flow profile that the fluids experience: (i) laminar flow which is a regular, smooth, and well-defined flow with relatively low flow rate; (ii) turbulent flow which is an irregular, chaotic, and ill-defined flow with relatively high flow rate characterized by the formation of eddies within the fluid; and (iii) cavitation flow which is an extremely complex flow because of the formation of small cavities that implode and generate shock waves. The tendency for one flow regime is a consequence of the balance of viscous and inertial forces acting on the fluid expressed by the Reynolds number:

$$Re = \frac{\text{inertial forces}}{\text{viscous forces}} = \frac{L v \rho_c}{\eta_c}$$

where L is some characteristic length of the system, v is the average fluid flow velocity, ρ_c is the density of the fluid, and η_c is the viscosity of the

fluid. When the viscous forces generated within a fluid dominate the inertial forces (low Re), the flow profile is laminar; when the inertial forces dominate (high Re) in the flow profile, it is turbulent. The size of the droplets produced by a homogenizer depends on a balance between the two opposing physical processes: droplet disruption and droplet coalescence. The interfacial forces that tend to hold the droplets together and the disruptive forces generated within the homogenizer that tend to pull the droplets apart are involved in droplet disruption process. To deform and disrupt a droplet during homogenization, it is necessary to apply an external force that is significantly larger than the interfacial force. The interfacial force is described by the Laplace equation:

$$\Delta P = \frac{4\gamma}{d}$$

where γ is the interfacial tension between the two liquids, d is the droplet diameter, and ΔP is the Laplace pressure which acts across the interface toward the center of the droplet. The equation indicates that the pressure required to disrupt a droplet increases as the interfacial tension increases or as the droplet size decreases. For a droplet to be broken up during homogenization, the disruptive forces must exceed the interfacial forces and their duration must be longer than the time required for droplet deformation. The relative magnitude of disruptive and interfacial forces is characterized by the Weber number (We):

$$We = \frac{\text{disruptive forces}}{\text{interfacial forces}}$$

Emulsification, Table 1 The type of homogenizers used for emulsification

Homogenizer type	Droplet formation mechanism	Productivity	Droplet size and size distribution	Energy density (J m^{-3})
High-speed mixer	Droplets break up in TI, TV, and LV flow regime	Batch or continuous	$>2 \mu\text{m}$, polydisperse	Low-high
Colloid mill	Droplets break up in LV and TV flow regime	Continuous	$>1 \mu\text{m}$, polydisperse	Low-high $10^3\text{--}10^8$
High-pressure homogenizer	Droplets break up in TI, TV, LV, and CI flow regime	Batch or continuous	$>0.1 \mu\text{m}$, polydisperse	Medium-high $10^6\text{--}10^8$
Ultrasonic	Droplets break up in CI flow regime	Continuous	$>0.1 \mu\text{m}$, polydisperse	Medium-high $10^6\text{--}10^8$
Microfluidization	Droplets break up in TI and TV flow regime	Batch or continuous	$<0.1 \mu\text{m}$, polydisperse	Medium-high 10^6 to 2×10^8
Membrane	Droplet detachment by wall shear stress	Continuous	$>0.3 \mu\text{m}$, narrow	Low-medium $<10^3\text{--}10^8$

TI turbulent inertial, TV turbulent viscous, LV laminar viscous, CI cavitational

During homogenization droplet-droplet collisions are particularly rapid because of the intense mechanical agitation of the emulsion. Droplet coalescence will depend on the time taken for the emulsifier to be adsorbed to the surface of the droplets relative to the time between droplet-droplet collisions. The flow profile and the nature of the emulsifier used influenced these times.

The characteristics of the different type of homogenizers are reported in Table 1.

High-speed mixer and colloid mills are suitable for preparing emulsions with relatively large droplet sizes ($>1 \mu\text{m}$), while the other types of homogenizers can be used to prepare submicron droplets. High-speed mixers, ultrasonic homogenizers, microfluidizer, and membrane homogenizers can be used for primary emulsification, whereas high-pressure valve homogenizers and colloid mills are most suitable for secondary emulsification. Most of these homogenizers have high productivity and they are able to work in a batch or continuous operation mode. In particular, membrane homogenizers have appreciably lower productivity than the other major types of homogenizers. The use of membrane homogenizers may be particularly useful where narrow droplet size distributions are important such as for drug delivery.

Emulsification by Membrane Operations

Emma Piacentini and Lidieta Giorno
Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Emulsions can be generated using membrane operations by: (i) *direct membrane emulsification*, where a microporous membrane is used to disperse one of two immiscible liquids as a form of droplets into another liquid or by (ii) *premix membrane emulsification*, where a coarse emulsion is extruded through the membrane pores in order to generate fine droplet emulsion. A pressure is required to cause the dispersed phase to permeate through the membrane. If any shear is applied on the membrane surface, droplets can be spontaneously detached from the pore outlets on the action of the interfacial tension when they reach a certain size. The method is referred as *static membrane emulsification* (Kukizaki 2009). The shear on the membrane surface can be generated by moving the continuous phase or using moving membranes. The method is referred as *dynamic membrane emulsification*. The shear stress is generated by the continuous phase flowing tangentially to the membrane surface (*cross-flow membrane emulsification*) (Williams et al. 1998) or stirred

Emulsification by Membrane Operations, Table 1 Different membrane operations used for the production emulsion droplets

	Advantages	Disadvantages
Dynamic membrane emulsification		
Stirred ME 	Suitable for low volumes of continuous phase Useful to study the effect of different experimental conditions on the emulsion preparation	Emulsion production at batch scale The shear stress at the membrane surface is nonuniform and depends on the cell geometry
Cross-flow ME 	Constant shear stress at the membrane surface Suitable for large-scale production and continuous or semicontinuous operation	Emulsion droplet breakup as a consequence of the recirculation High dispersed phase concentration is obtained after a long time of operation
Cross-flow ME with static promoter 	Constant shear stress at the membrane surface Suitable for large-scale production and continuous or semicontinuous operation Suitable to prevent droplet breakup	High dispersed phase concentration is obtained after a long time of operation
Pulsed-flow ME 	Suitable for large-scale production and continuous or semicontinuous operation Able to prevent droplet breakup High dispersed phase concentrations obtained in a single pass	—
Rotating ME 	Suitable for large-scale production and continuous or semicontinuous operation Able to prevent droplet breakup High dispersed phase concentrations obtained in a single pass	Complicated and more expensive design Higher power consumption

(continued)

Emulsification by Membrane Operations, Table 1 (continued)

	Advantages	Disadvantages
Vibrating ME 	Suitable for large-scale production and continuous or semicontinuous operation Able to prevent droplet breakup	Complicated and more expensive design Higher power consumption Nonuniform temporal distribution of shear stress on the membrane surface
Static membrane emulsification		
	Simple experimental setup Low energy input Able to prevent droplet breakup	Emulsion production at batch scale The production of uniform droplets is possible only at low dispersed phase flux with low productivity

(*stirred membrane emulsification*) (Stillwell et al. 2007). The use of static turbulence promoters in cross-flow membrane emulsification allows increasing the shear stress at the membrane surface while maintaining a low value along the circuit out of the membrane (Koris et al. 2011). Alternatively, a periodic flow pulsation is generated in the continuous phase without recirculation (*pulsed-flow membrane emulsification*) (Holdich et al. 2013). Moving membranes can be used instead of the commonly used stationary membranes. The droplet detachment from the membrane surface is controlled by rotating (Vladislavljević and Williams 2006) or vibrating (Holdich et al. 2010) the membrane within an otherwise static continuous phase. Membrane operations used for the production emulsion droplets are described in Table 1.

Emulsification by membrane operation is controlled by:

- Membrane parameters, including porosity, mean pore size, pore geometry, pore distance, and membrane surface wettability
- Phase parameters, including interfacial tension, emulsifier type and concentration, viscosity and density of dispersed and continuous

phases, phase composition, pH, and ionic strength

- Process parameters, including wall shear stress, transmembrane pressure, membrane module configuration, and temperature

Comparing to the conventional emulsification processes, emulsification by membrane operation permits to obtain a better control of droplet size and droplet size distribution, low energy and material consumption, and modular and easy scale-up. Nevertheless, productivity (m³/day) is much lower, and therefore the challenge in the future is the development of new membranes and innovative membrane operations to keep the known advantages and maximize the productivity.

Emulsifier

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Emulsifiers are a class of molecules with surface active properties (Dickinson 2009). This behavior is due to their amphiphilic structure which

contains both a polar or hydrophilic head and a nonpolar or hydrophobic tail (Fig. 1). A measure of the degree to which an emulsifier is hydrophilic or lipophilic is given by the hydrophilic-lipophilic balance (HLB) determined by calculating values for the different regions of the molecule. Emulsifiers adsorb at interfaces between two immiscible liquid anchoring its hydrophilic part into water and its lipophilic part into oil decreasing the interfacial tension between them (Fig. 1). This facilitates droplets disruption during homogenization and, in the case of membranes, lowering the minimum emulsification pressure. Emulsifiers have an important role in emulsion stabilization against droplets coalescence and/or aggregation providing electrostatic repulsion, steric repulsion, and/or strength to the interfacial layer of the droplets.

Emulsifiers are normally classified according to the head group type as ionic (anionic and cationic), nonionic, and amphoteric (zwitterionics). Anionic emulsifiers contain anionic functional groups at their head, such as sulfate (sodium dodecyl sulfate, SDS), sulfonate, phosphate, and carboxylates. Cationic emulsifiers contain cationic functional groups at their head, such as pH-dependent primary, secondary, or tertiary amines and permanently charged quaternary ammonium cation (cetyl trimethylammonium bromide, CTAB). Nonionic emulsifiers have polar headgroups and they include glycol and glycerol esters, polyoxyethylene esters,

Emulsifier,

Fig. 1 Emulsifier structure and emulsifier distribution at water-in-oil and oil-in-water emulsion interface

polyoxyethylene ethers, polyoxyethylene–polyoxypropylene copolymers, sorbitan derivatives, and sucrose esters. Zwitterionic (amphoteric) emulsifiers have both cationic and anionic centers attached to the same molecule. The cationic part is based on primary, secondary, or tertiary amines or quaternary ammonium cations. The anionic part can be more variable and include sulfonates, sultaines, betaines, and phosphates (lecithin).

A variety of emulsifiers are natural products derived from plant or animal tissue such as hydrocolloids (high molecular weight polysaccharides) and proteins.

Emulsifiers

► Amphiphilic Molecules

Emulsion

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

An emulsion consists of two immiscible liquids (usually oil and water) with one of the liquids (dispersed phase or internal) dispersed as a form of spherical droplets in the other (continuous phase or external) (Israelachvili 1994). Depending upon the nature of the dispersed phase, the emulsions are classified as (i) oil-in-water emulsions (O/W) consisting of oil droplets dispersed in an aqueous phase and (ii) water-in-oil emulsions (W/O) consisting of aqueous droplets dispersed in an oil phase. It is also possible to prepare various types of

multiple emulsions, for example, water-in-oil-in-water emulsions (W/O/W), in which water droplets are dispersed within larger oil droplets which are themselves dispersed in an aqueous phase and oil-in-water-in-oil emulsions (O/W/O) consisting of oil droplets dispersed in larger water droplets which are themselves dispersed in an oil phase.

The preparation of an emulsion is termed emulsification and the agents used for this purpose are termed emulsifiers. Other agents, such as emulsion promoters or stabilizers, are often added to an emulsion to promote the emulsifying process, for example, by increasing the viscosity or providing a protective colloid action. The preparation of emulsions involves breaking up the internal phase by supplying mechanical or chemical energy. When an emulsion is formed, the interface between the phases is considerably increased as a result of the droplet formation. The liquid always tends to reduce its surface or interface to a minimum; therefore, an increase in interface is possible only if energy is supplied. The work that must be expended on drop division is:

$$dA = \gamma dI$$

where dA is the work to be expended and dI is the increase in interface. The proportionality factor is the interfacial tension γ between the phases to be emulsified. Thus, if the interfacial tension between the two phases is high, considerable mechanical energy is required for emulsification unless an emulsifier is added; if the interfacial tension is low, little mechanical energy is consumed.

According to the droplet size, emulsions are classified as follows:

- Macroemulsions: these usually have a size range of 0.1–5 μm .
- Nanoemulsions: these usually have a size range of 20–100 nm.
- Micellar emulsions or microemulsions: these usually have a size range of 5–50 nm.

If the droplet size exhibits a wide statistical distribution, the emulsion is described as polydisperse, in contrast to monodisperse systems with a

Emulsion, Fig. 1 The various breakdown processes in emulsions

uniform droplet size. The ideal particle size depends on the available methods of preparation and industrial application in each case. Another important emulsion property is the ratio of the volume of the dispersed phase (V_i) to the volume of the continuous phase or (V_c) is called the phase volume ratio (Φ). If $\Phi < 0.43$ ($V_i = 30\%$ of total volume), the flow properties of the emulsion are determined primarily by the continuous phase. If $\Phi > 0.43$, the viscosity of the emulsion generally increases. As Φ increases, either phase reversal or cream formation occurs.

Emulsion stability should match its application. Thus, for a number of applications, the emulsion should be stable under very specific conditions, but it should break after its purpose has been achieved according to a specific condition (such as temperature, pH, or salts, or the like). An emulsion is stable if fusion of the droplets is prevented by a sufficiently high energy barrier (Tadros 2013). In general, the energy barrier is built up by the film of emulsifier that forms at the surface of the droplets. Several breakdown processes may occur on storage depending on

particle size distribution and density difference between the droplets and the medium (Fig. 1).

In sedimentation, the uniform dispersion of the droplets is disturbed by aggregation, which leads to settling or creaming of the internal phase. This process results from external forces usually gravitational or centrifugal. When such forces exceed the thermal motion of the droplets (Brownian motion), a concentration gradient builds up in the system with the larger droplets moving faster to the top (if their density is lower than that of the medium) or to the bottom (if their density is larger than that of the medium) of the container. To keep an emulsion stable, such aggregation must be prevented since droplet aggregates sediment faster than individual small droplets. Sedimentation is not always necessarily accompanied by coalescence. Although the distribution has been altered, the original dispersion can be restored by shaking or stirring. Flocculation refers to aggregation of the droplets (without any change in primary droplet size) into larger units. It is the result of the van der Waals attraction that is universal with all disperse systems. Flocculation

occurs when there is no sufficient repulsion to keep the droplets apart to distances where the van der Waals attraction is weak. Flocculation may be “strong” or “weak,” depending on the magnitude of the attractive energy involved. One way to overcome the van der Waals attraction is by electrostatic stabilization using ionic surfactants, which results in the formation of electrical double layers that introduce a repulsive energy that overcomes the attractive energy. The second and most effective method of overcoming flocculation is by “steric stabilization” using nonionic surfactants or polymers. Ostwald ripening (disproportionation) results from the finite solubility of the liquid phases. Liquids that are referred to as being immiscible often have mutual solubilities that are not negligible. With emulsions, which are usually polydisperse, the smaller droplets will have larger solubility when compared with the larger ones (due to curvature effects). With time, the smaller droplets disappear and their molecules diffuse to the bulk and become deposited on the larger droplets. With time, the droplet size distribution shifts to larger values. Several methods may be applied to reduce Ostwald ripening: (i) Addition of a second dispersed phase component that is insoluble in the continuous medium. In this case, partitioning between different droplet sizes occurs, with the component having low solubility expected to be concentrated in the smaller droplets. During Ostwald ripening in a two-component system, equilibrium is established when the difference in chemical potential between different size droplets (which results from curvature effects) is balanced by the difference in chemical potential resulting from partitioning of the two components. This effect reduces further growth of droplets. (ii) Modification of the interfacial film at emulsion interface. By using surfactants that are strongly adsorbed at the emulsion interface (i.e., polymeric surfactants) and that do not desorb during ripening (by choosing a molecule that is insoluble in the continuous phase), the rate could be significantly reduced. In coalescence, the individual droplets fuse together. First, the smaller droplets are

absorbed by the larger droplets, and then increasingly larger drops merge together until two continuous phases are finally formed. The driving force for coalescence is the surface or film fluctuations which results in close approach of the droplets whereby the van der Waals forces is strong thus preventing their separation. Two droplets can only coalesce if the intervening layer of liquid is pierced when they approach each other. Therefore, coalescence is opposed in two ways by the emulsifier film surrounding the droplets. First, as in the case of aggregation, the like charges of the electrical double layer prevent them from approaching each other. Second, the buildup of an elastic surface film causes the emulsion droplets to bounce off each other when they collide. Coalescence is always followed by accelerated settling or creaming, which destroys the emulsion completely. The emulsion is then broken and cannot be reconstituted by shaking or stirring. The driving force for prevention of coalescence is to produce a stable film that can be achieved by two mechanisms and their combination: (i) increased repulsion both electrostatic and steric and (ii) dampening of the fluctuation. In general, smaller droplets are less susceptible to surface fluctuations and hence coalescence is reduced. This explains the high stability of nanoemulsions. The phase inversion refers to the process whereby there will be an exchange between the disperse phase and the medium. For example, an O/W emulsion may with time or change of conditions invert to a W/O emulsion. In many cases, phase inversion passes through a transition state whereby multiple emulsions are produced. Phase inversion of emulsions can be one of two types: transitional inversion induced by changing the factors that affect the HLB of the system, for example, temperature and/or electrolyte concentration, and catastrophic inversion, which is induced by increasing the volume fraction of the disperse phase.

Emulsions have application in several industrial systems such as food emulsion, for example, mayonnaise, salad creams, deserts, and beverages; personal care and cosmetics, for example,

hand creams, lotions, hair sprays, and sunscreens; and pharmaceuticals, paints, and bitumen emulsions.

Emulsion Characterization

Volker Gaukel, Heike Schuchmann and Richard Bernewitz

Food Process Engineering, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

The production of emulsions via membrane processes is investigated since 30 years and started with investigations from Nakashima et al. with porous glass membranes (Nakashima et al. 1991). There are several principles of membrane emulsification as, e.g., direct emulsification and premix emulsification. But nevertheless which process is used, the characterization of the emulsion is an important issue.

Besides the emulsion's ingredients, which are defined by the manufacturer, there are many structure parameters which influence the physical stability, the color, the rheological behavior, or the controlled release properties of the emulsion.

If the kind of emulsion is not known, the first characterization method must identify if it is an oil in water (o/w) or water in oil (w/o) emulsion. In many cases this can be easily done by a dilution test. This means that an o/w emulsion can be diluted with a hydrophilic phase and w/o emulsions can be diluted with a hydrophobic phase. Measurement of conductivity of the emulsion is another possibility as o/w emulsions have in general a much higher conductivity than w/o emulsion.

These tests cannot identify if a double emulsion (e.g., oil in water in oil phase) is present. This must be investigated with microscopic methods.

The two main characteristics of an emulsion, which influence the physical stability, the color, and the rheological behavior, are the drop size distribution (DSD) and the disperse phase content (DPC) (Schuchmann 2007).

The DPC is set by the manufacturer and is constant when using premix membrane emulsification. Using other membrane emulsification processes like cross flow devices, the DPC of emulsions is adjusted by the rate of flow of the oil and water phase or by recirculation time of the continuous phase/emulsion and changes continuously. Regarding multiple emulsions, additional instability mechanisms may lead to changes of DPC while emulsifying and storing. The DPC can be measured with differential scanning calorimetry (DSC) (Schuch et al. 2013; Dalmazzone et al. 2009), NMR (Bernewitz et al. 2011; van Duynhoven et al. 2007), or rheological characteristics of single and double emulsions.

The DSD depends on several factors as the kind and pore size of the membrane, the transmembrane flux, the shear forces at the membrane surface, as well as the composition of the emulsion (kind of emulsifier, viscosity of the phases, etc.). The DSD can be measured with various methods which are referred here. The DSD can also change during storage and distribution of an emulsion leading to a product deterioration and phase separation. A rough indication for the physical stability of an emulsion can be the zeta potential (ζ), whereas $\zeta > 30$ mV indicates a stable emulsion. Another method is a Dynamic Mechanical Analysis (DMA) of the emulsion (Brummer 2006).

As the changes of DSD are often very slow and cannot be monitored over the whole shelf life of a product, there are several test procedures to accelerate this process. A procedure is to rise the storage temperature from room temperature to 40–50 °C which accelerates the deterioration processes by the factor 2. Other means are the exposure of the emulsion to many short temperature abuses or to a centrifugal field which can shorten the monitoring time by the factor 10–2,000. It should be kept in mind that all the acceleration

techniques may change the structure of the emulsion and may lead to differing results compared to real storage conditions.

Emulsion Liquid Membrane (ELM)

Vladimir S. Kislik
Campus Givat Ram, Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

Emulsion liquid membrane, ELM, is a system in the form of double emulsions (for details, see Chakraborty et al. 2010). It may be of two types: water-in-oil emulsion dispersed in an external

aqueous phase and oil-in-water emulsion dispersed in an outer organic phase. The membrane phase in the water-in-oil-in-water (W/O/W) type is the immiscible oil phase separating the aqueous phases, while in the O/W/O type, the immiscible water phase separating the two organic phases acts as the LM. Hence, the liquid membrane serves here a dual purpose: (a) permitting selective transfer of one or more components through it from external phase to internal droplets and vice versa and (b) preventing mixing of external and internal phases. The emulsion is dispersed in the feed solution, and mass transfer from the feed to the internal receiving phase takes place. ELMs were first used for separation of hydrocarbons from wastewater with high separation efficiency. Compared to conventional processes, emulsion liquid membrane (ELM) process has some attractive features, for example, simple operation, high efficiency, extraction and stripping in one stage, larger interfacial area, and scope of continuous operation.

Since an ELM is a thin film of liquid (oil or aqueous) composed of surfactants and their solvents between a feed and a receiving phase, any immiscible liquid can serve as a membrane between two liquid or gas phases containing a solute at different concentrations. If the solute is soluble in the membrane phase and has a reasonable diffusivity through the membrane, then its selective transport through the membrane from higher to lower concentration can be achieved. This type of permeation has simple mechanism and not of much technical importance.

At facilitated transport mechanism, liquid membrane incorporates a reactive component or carrier, reacting reversibly and selectively with species of interest to carry the formed complexes across the LM to the internal phase, and dissociates, discharging the solute to the internal phase. The unchanged carrier then diffuses back to the membrane-external phase interface (see Fig. 1). A small amount of carrier is required in the membrane phase even for achieving a high degree of separation. At different proton concentrations in the aqueous phase or using another ions, ion exchange processes between two LM surfaces occur. This phenomenon is called coupled mass transport. If the transports of these two different species occur

Emulsion Liquid Membrane (ELM), Fig. 1 Schematic representation of the liquid membrane globule and concentration profile of solute through ELM

in the same direction, it is called cotransport, while transport in opposite direction is called countertransport. Evidently the process leads to the transport of targeted ionic species across the membrane against their concentration gradient. This so-called “uphill” transport will continue until one driving factor (difference of chemical potentials) is balanced by the difference between chemical potentials of another transported ion.

The ELM technique has great potential for recovery and removal of different metal ions. Separation of metals like copper, zinc, cadmium, cobalt, nickel, mercury, uranium, chromium, rhenium, and several others, including noble metals like gold and silver, lanthanides, and rare earths, was studied. To date, there are two industrial plants installed for zinc recovery from wastewater in Austria, having a capacity of 75 m³/h and 700 m³/h, removing zinc selectively from 500 to 3 ppm. Bis(2-ethylhexyl) dithiophosphoric acid

has been used as carrier. One more plant with the 200 m³/h capacity in Germany and the 200 m³/h capacity plant in the Netherlands.

Weak acids like phenol and cresol and weak bases like ammonium and amines have been successfully removed from wastewater. Among them, the separation-concentration of phenol has been intensively investigated. Phenol removal from wastewater was commercialized in China. Phenol is removed from about 1,000 ppm to 0.5 ppm with an extraction efficiency of greater than 99.95 %.

ELM technology has been applied to a great extent for separation of mixtures of saturated and aromatic hydrocarbons, of amino acids, and of strong acids like nitric acid and thiocyanate. Cyanide removal from wastewater in gold processing is commercialized in China. Cyanide is reduced from about 130 ppm to 0.5 ppm with an extraction efficiency of 99.6 %.

ELM has promise in the fields of biotechnology and biomedicine and has found application in the separation of organic acids, fatty acids, purification of antibiotics, enzyme-catalyzed reactions, and detoxification of blood.

Emulsion Liquid Membrane for Wastewater Treatment

N. Othman
Faculty of Chemical and Energy Engineering,
Universiti Teknologi Malaysia, Skudai, Johor,
Malaysia

Emulsion liquid membranes are known as double emulsion system. The advantage of this process is extraction and stripping process occurred

simultaneously in one single-step operation, and equilibrium limitation can be removed. It also can reduce the amount of expensive extractant; high fluxes and high selectivity are possible. It is also possible to treat any source of wastewater containing organics and metals even at low concentration. The primary emulsions of water in oil emulsion were prepared by emulsifying two immiscible phases of the stripping solution and organic liquid membrane phase with a surfactant to produce an emulsion. This primary emulsion is then dispersed in the solution or phase to be treated. Mass transfer takes place between the feed phase and the internal phase through the liquid membrane phase. The illustration and schematic diagram of the process is shown in Fig. 1. The organic liquid membrane may contain a carrier to facilitate the extraction process. The carrier will act as a shuttle to carry the solute from external interface to the internal interface or receiving

phase. At the external interface, the carrier will form carrier-solute complexes and diffuse to the internal interface and release the solute into the receiving phase by the reaction with the stripping agent. For example, in metal separation from wastewater, even in very low concentration, the carrier will selectively combine with the solutes to form a metal-carrier complex, and the complex will permeate through the membranes from the outer to the inner interface. At the inner interface, the complex decomposes by the reversal of the equilibrium reaction, and the metal ion is liberated into the internal phase and the regenerated carrier goes back into the membrane phase. The mechanism of removal and recovery of the solute/metal assisted by the carrier is illustrated in Fig. 2.

The major problem associated with ELMs in the wastewater treatment is emulsion stability. If the emulsion globules break and the inner droplet phase spills into the continuous phase, the separation is lost. Interfacial shear between the continuous phase and membrane phase causes the liquid membrane to thin and, in some cases, rupture.

Another problem is osmotic swelling although it is rarely mentioned in the literature. This phenomenon occurs when water in external phases diffuses through the organic membrane phase and swells the inner aqueous droplet phase. The increased volume of the internal phase leads to increased breakage and dilution of the concentrated solute in the droplet phase.

For the last three decades, this method has attracted many studies in the area of hydrometallurgy such as separation of metal ions either from wastewater or from ores (Othman et al. 2006; Reis and Carvalho 1993; Reed et al. 1987; Marr 1984;

Emulsion Liquid Membrane for Wastewater Treatment, Fig. 1 A schematic diagram of emulsion liquid membranes

Emulsion Liquid Membrane for Wastewater Treatment, Fig. 2

The mechanism of couple transport in emulsion liquid membrane

Draxler and Marr 1986; Babcock et al. 1986). It has been reported that emulsion liquid membrane system has been successfully used to recover copper selectively from waste stream of mine solutions (Wright et al. 1995).

From the viewpoint of practical application in wastewater treating processes, recovery processes for copper (Volkel et al. 1980; Goto et al. 1989a), uranium (Hayworth et al. 1983), and zinc (Marr 1984) were examined in test plant. The first application of emulsion liquid membrane (ELM) on an industrial scale was the process to remove zinc from wastewater at a textile plant in Austria (Draxler and Marr 1986).

In order to get a better understanding of emulsion liquid membrane process and the system potentials, the extraction performance must be studied based on the kinetics and thermodynamic aspects. The parameters that affect the solute extractability and selectivity should be identified. The parameters such as stripping agent types and acidity that control the mass transfer of solute, volume ratio of emulsion to external phase that affects the mass transfer area of extraction process, and carrier concentration, type of diluents, swelling, residence time, and agitation rate that control the extraction performance and the breakup rate of emulsion should be studied.

Emulsion Pertraction Technology for Zinc Recovery

Immaculada Ortiz and Eugenio Bringas
Department of Chemical and Biomolecular
Engineering, University of Cantabria, Santander,
Cantabria, Spain

The emulsion pertraction technology (EPT) is a separation process that combines the ability of liquid membranes to promote the uphill transport of target species by the coupling between mass transfer and chemical reaction and the benefits of using membrane contactors, namely, large interfacial area, nondispersive contact, and independent flow of the fluid phases. Figure 1 shows the flow diagram of the EPT process that comprises two essential process units: a microporous hollow fiber membrane contactor (see Fig. 2) and the emulsion vessel that contains a pseudo-emulsion consisting of the organic phase formulated with a selective organic carrier and the dispersed stripping solution. The target solute is chemically transferred from the aqueous feed to the organic phase that is embedded in the pores of the hollow fibers due to their hydrophobic character. Next, the solute-carrier complex diffuses to the interface between the organic and the droplet of stripping phase where the back-extraction reaction occurs. The solute is recovered from the internal aqueous phase after emulsion settling (San Román et al. 2010; Urtiaga et al. 2010; Carrera

Emulsion Pertraction Technology for Zinc Recovery, Fig. 1 Performance of the EPT process

et al. 2009; Bringas et al. 2006; Uriaga et al. 2005; Klaassen and Jansen 2001). In the forthcoming section, the potential of the EPT technology to develop separation processes with zinc recovery is evaluated.

Recovery of Zinc from Liquid Wastes by EPT

Zinc's electropositive nature makes it well-suited for use as a coating for protecting iron and steel products from corrosion. For this reason, the surface treatment industry accounts for almost half zinc modern-day demand. The processes involved in the surface treatment of components are predominantly water-based, and thus the generation and management of complex liquid wastes is an issue of concern (Bringas et al. 2012). EPT has been proven to be an efficient technology to perform both the selective removal and recovery of zinc from different wastes produced in the context of surface treatment industry: (i) spent pickling acids (SPA) generated in the hot-dip galvanizing process (see composition in Table 1) and (ii) spent chromium-based passivation baths (SPB)

employed in zinc electroplating operations (see composition in Table 1).

Figures 3 and 4 depict the separation and recovery objectives to be achieved by the application of EPT to the treatment of SPA and SPB.

Under the usual composition of SPA, zinc forms anionic chlorocomplexes ($ZnCl_4^{2-}$ and $ZnCl_3^-$) while iron is present in the form of neutral or cationic compounds (Regel et al. 2001). Tributyl phosphate (TBP) and water are reported as the most suitable extraction and back extraction reagents enabling the selective separation and concentration of zinc with minimum iron extraction (Cierpezewski et al. 2002). On the other hand, the information provided by the equilibrium isotherms depicted in Fig. 5 confirms the commercial selective carrier bis(2,4,4-trimethylpentyl) phosphinic acid (Cyanex272) as a suitable reagent to formulate the liquid membrane due to its capacity to selectively separate Fe^{3+} and Zn^{2+} (tramp ions) from chromium under the typical pH conditions (1.8–2.5) of the passivation baths. Sulphuric acid is selected as stripping agent (Uriaga et al. 2010).

Figure 6 shows the kinetic results obtained with the SPA-TBP-water and the EPT process.

Emulsion Pertraction Technology for Zinc Recovery,

Fig. 2 Characteristics of hollow fiber contactors for a bench scale EPT process

Parameter/Characteristic	Value/Description
Fiber material	Polypropylene
Shell material	Polypropylene
Type of fiber	X-50
Internal diameter of the fiber	240 μm
Thickness	30 μm
Average pore diameter	0.04 μm
Porosity	40%
Effective lenght	0.15
Interfacial area	1.4 m^2
Number of fibers	10200

Emulsion Pertraction Technology for Zinc Recovery,

Table 1 Physical-chemical properties of spent pickling acids (SPA) and spent chromium-based passivation baths (SPB)

SPA		SPB	
Parameter	Value	Parameter	Value
pH	≈ 0	pH	1.8–2.5
Zn^{2+} (mg/L)	122,000	Zn^{2+} (mg/L)	2500–11,780
Fe^{2+} (mg/L)	100,000	Fe^{3+} (mg/L)	20–90
Cl^- (mg/l)	300,000	Cr^{3+} (mg/L)	4500–9350
Free acidity, H^+ (mol/L)	1	NO_3^- (mg/L)	67,520

It is concluded that the extraction (EX) and back-extraction (BEX) percentages of zinc and iron, when steady state conditions (regarding zinc kinetics) are reached, are respectively, 79 % (EX Zn), 98 % (BEX Zn), 23 % (EX Fe), and 38 % (BEX Fe). Under these operation conditions, the maximum value of selectivity of zinc over iron in the stripping solution is 15 kg of Zn/kg of iron (Ortiz et al. 2004; Samaniego et al. 2006; Samaniego et al. 2007; Carrera et al. 2009; Bringas et al. 2012). On the other hand, the efficiency of the EPT process to carry out the regeneration of real passivation baths is demonstrated in Fig. 7 which shows reductions

Emulsion Pertraction Technology for Zinc Recovery, Fig. 3 Treatment of spent pickling acids by EPT with zinc recovery

Emulsion Pertraction Technology for Zinc Recovery, Fig. 4 Regeneration of chromium-based passivation baths by EPT with zinc recovery

Emulsion Pertraction Technology for Zinc Recovery,

Fig. 5 Extraction isotherms of iron, zinc and chromium with Cyanex272

Emulsion Pertraction Technology for Zinc Recovery,

Fig. 6 Evolution with time of iron (discontinuous line) and zinc (continuous line) concentration in the SPA and stripping solution (0.5 L of SPA with the composition indicated in Table 1; 1 L of organic solution containing 50 % v/v TBP in Shellsol D70; 1 L of water)

Emulsion Pertraction Technology for Zinc Recovery,

Fig. 7 Extraction percentages and concentrations in the stripping solution after 3 h of EPT regeneration of SPB using Cyanex272 as selective extractant

in the zinc and iron contents higher than 80 % after 3 h of experimental running with an almost negligible variation of the chromium concentration. Furthermore, zinc is selectively recovered in the stripping solution (concentration $>35 \text{ kg/m}^3$) being the concentrations of iron ($<0.45 \text{ kg/m}^3$) and chromium ($<0.003 \text{ kg/m}^3$) almost negligible (Urriaga et al. 2010; Bringas et al. 2011; Diban et al. 2011; Bringas et al. 2012).

Therefore, these results confirm the EPT process as a suitable alternative to perform the treatment of spent pickling acids and spent passivation baths allowing at the same time the zinc recovery for further reuse as was illustrated by Figs. 3 and 4.

Future Directions

Future development will require research and development activities in the following areas:

1. Determination of the optimal operational conditions to: (i) maximize the extraction and back-extraction kinetics and (ii) achieve maximum values of selectivity which permit the exploitation of the different process streams generated after the application of the EPT process.
2. Analysis of the long-term performance of the separation process to evaluate the stability of the selective carrier which guarantees the process' economic viability.

Emulsion Rupture by Membranes

Jose Coca

Department of Chemical and Environmental Engineering, University of Oviedo, Oviedo, Spain

Emulsions are homogeneous mixtures that consist of a dispersed phase (oil droplets in O/W emulsions) distributed uniformly in a continuous phase (water). Ultrafiltration (UF) and microfiltration (MF) membranes have been used for the treatment of O/W emulsions produced in industries such as steel works, metal finishing, pharmaceuticals, cosmetics, food, etc. Oil droplets are recovered as retentate and the aqueous phase permeates the membrane. The production of 1 t of steel may demand up to 200 t of water, the largest water usage corresponding to the rolling mills. Membrane performance diminishes when oil droplets fall below the micron range and problems become more pronounced when ionic surfactants are present, as they increase repulsive forces between droplets.

Demulsification is commonly achieved by chemical or electrostatic methods. Chemical demulsification destabilizes the disperse phase by two mechanisms: *coagulation* (inorganic salts) and *flocculation* (organic polymers). The disadvantage of chemical demulsification is that the bulk phase has to be further treated before discharge. Electrostatic demulsification is ineffective for emulsions with high water content and sparking during treatment may generate new compounds from the surfactant and the oil. However, membranes can be used as coalescers by forcing the emulsion through the pores of the membrane (Kajitvichyanukul et al. 2011).

Hydrophilic membranes induce coalescence of O/W emulsions while hydrophobic membranes can be used for the demulsification of W/O emulsions (Fig. 1). The main factors affecting membrane demulsification are (Daiminger et al. 1995; Hong et al. 2003; Kocherginsky et al. 2003):

Emulsion Rupture by Membranes, Fig. 1 Influence of membrane characteristics in oil droplet rejection

- Membrane pore size, transmembrane pressure (ΔP), and imposed in-pore shear rates affect coalescence. The smaller the membrane pore size and the lower ΔP , the better demulsification efficiency. However, small pores coupled with a low ΔP would lead to low permeation flux.
- If the ΔP is below a critical value (ΔP_c), the emulsion rejection can be maximized. Above a ΔP_c the membrane acts as a coalescer and the droplets wet the membrane enabling the oil droplets to coalesce.
- Membrane demulsification seems to be independent of the initial disperse phase concentration and membrane thickness.
- The demulsification process is determined by interactions between droplets and membrane surface.

So far, membranes as coalescers do not show great advantages with respect to conventional coalescing techniques, e.g., fiber-bed coalescence and electrostatic coalescers. New chemically treated ceramic membranes and silicon carbide supports have a great potential for oil-water applications since they are abrasion and solvent

resistant, easy to clean by backflushing, and have a low cost and longer life than the previous generation membranes.

Emulsion Separation by Membranes

Jose Coca

Department of Chemical and Environmental Engineering, University of Oviedo, Oviedo, Spain

Separation of oily emulsions from wastewaters is generally carried out by a combination of chemical and mechanical methods. Chemicals (coagulants and flocculants) are used to destabilize the oil-water interface allowing the oil droplets to coalesce. Mechanical methods include gravity-based settlers, skimmers, dissolved air flotation (DAF), centrifuges, electro-coalescers, etc.

Pressure-driven membrane processes (microfiltration MF, ultrafiltration UF, and reverse osmosis RO) may be used to separate oil and water phases. The water molecules move through the membrane (permeate) and a concentrated emulsion (retentate or concentrate) is obtained. Some components of the emulsion may also move through the membrane, depending on their characteristics and size and the nature of the

Emulsion Separation by Membranes, Fig. 1 Hybrid UF system for oily wastewater treatment

membrane, leading to contamination of the permeate. Fouling and scaling of the membrane lead to a poor performance and membrane cleaning procedures must be taken into account.

When MF is used for oil-water separation, particulates, emulsified oil, and microbial contaminants can be removed. Cross-flow velocities may range between 3 and 6 m/s and transmembrane pressures (TMPs) between 100 and 770 kPa. The main limitation of membrane processes is the decline of the permeate flux over time because of concentration polarization, membrane fouling (due to surfactant or oil adsorption on the pore walls), gel layer formation, pore blocking by oil droplets, pH, and temperature.

Often it is not possible to use a simple membrane system to perform an oil-water separation: some effluents may cause severe membrane fouling and pretreatment is necessary to maintain a high and steady flux. In these situations, *integrated-membrane or membrane-based hybrid processes* may be suitable alternatives to obtain good process performance and to extend membrane life (Coca et al. 2013). A typical membrane hybrid process for oily wastewaters is shown in Fig. 1.

Usually the process starts with the removal of settleable solids and free-floating oil prior to membrane treatment, mainly UF. This can be accomplished in a tank with free-oil removal equipment, such as a skimmer, or by a rotating brush strainer, a pressure or vacuum filter to remove solids, and a centrifugal separator or a hydrocyclone to remove oil and solids. The remaining oily wastewater (mainly stable O/W

emulsion) is then transferred to a process tank and pumped through the UF unit to remove the emulsified oil. The retentate containing the oil is recycled to the process tank, and the permeate is continuously withdrawn. This process is commonly used in the automobile industry (Cheryan and Rajagopalan 1998).

Emulsion Treatment with Membranes

Jose Coca
Department of Chemical and Environmental
Engineering, University of Oviedo, Oviedo,
Spain

An emulsion is a homogeneous mixture of two immiscible liquids, with one of them (typically oil) dispersed as droplets into the other. Emulsion droplets usually range between 0.1 and 20 μm in diameter. The two main categories of emulsions are

Emulsion Treatment with Membranes, Fig. 1 UF process for oily wastewater treatment

oil-in-water (O/W, >30 % water) and water-in-oil (W/O, <25 % water): water and highly polar liquids are hydrophilic, while nonpolar liquids are considered “oils”. Emulsions consist of two phases: an internal or discontinuous phase (finally divided droplets) and an external or continuous phase (which keeps the droplets in suspension), which are bound together at the interphase. A surfactant reduces the interfacial tension between the two phases binding them together. Industrial oily wastewaters can be classified as: *free oil* ($D_p \geq 150 \mu\text{m}$), *dispersed oil* ($D_p = 20\text{--}150 \mu\text{m}$), *stable emulsified oil* ($D_p \leq 20 \mu\text{m}$), and *dissolved oil* ($D_p \leq 5 \mu\text{m}$). Free oils and dispersed O/W emulsions can be removed by mechanical methods such as gravity settling, skimming, coalescence, centrifugation, etc. (Alther 1998; Stewart and Arnold 2008). Stable emulsified oils and dissolved oils cannot be removed efficiently by conventional methods because of the small droplet size and low oil concentration.

Membrane processes are increasingly being applied for treating O/W emulsions due to their advantages: high-quality permeate and removal efficiency, lower capital costs than with thermal processes, and compact design. Some of the most promising membrane O/W treatments are dehydration of emulsions by pervaporation, reverse

osmosis (RO), flocculation followed by microfiltration (MF), MF, membrane distillation, nanofiltration (NF), and ultrafiltration (UF) (Cheryan 1998; Chakrabarty et al. 2010).

A typical UF-based system for oily wastewaters, operated in a semi-batch recycle mode, is shown in Fig. 1. The final concentrate volume may be only 3–5 % of the initial oily wastewater volume. The system must be cleaned after a certain time to restore the permeate flux. O/W emulsions may be reduced by 85–90 % by volume and with an oil concentration in the retentate of 70–75 %.

MF or UF processes cannot remove dissolved oil components in water. For that purpose, other methods, such as RO or NF, are required. The choice of membrane material is important: inorganic membranes are chemically robust and expensive; polymeric membranes have lower resistance to aggressive feeds and are more susceptible to fouling, but are considerably cheaper. In spite of the fact that effluent oil concentrations of 5 ppm or less can be achieved with membranes, they have not found wide practical applications so far. Membrane systems suffer from concentration polarization and fouling problems that lead to a substantial flux decline with time. Membranes must be replaced every 3–5 years.

O/W emulsions can sometimes be treated by a combination of two membrane processes (e.g., UF/NF, UF/RO or NF/RO) to obtain a high-quality water effluent.

Emulsions' Drop Size Distribution, Measurement of

Volker Gaukel, Richard Bernewitz and Heike Schuchmann
Food Process Engineering, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

The drop size distribution (DSD) of an emulsion has influence on the physical stability, the color, and the rheological behavior of the emulsion and is therefore an important means of characterization.

The DSD can be measured with various methods. In principle one can distinguish between methods which measure physical characteristics of single drops or physical characteristics of the bulk emulsion. The latter are often used for the characterization of an emulsion in terms of quality control where it is only necessary to notice differences between a reference and a product or where it is sufficient to attain the DSD results only after a calibration against a system with known DSD. Examples are rheological behavior, dielectric spectrometry, dynamic scanning calorimetry, focused beam reflectance, or dynamic reflection measurements. An advantage of these methods is

often that they are fast and may be used online or at least without diluting the sample.

For the measurement of DSD, a physical characteristic which is connected to the drop size of a single drop-like sedimentation velocity, diffraction of light at the drop surface, projected area in a microscopic image, etc., is necessary. This makes clear that the basis of the calculation of DSD varies between different methods, and one should not expect the same DSD results from different measuring methods. In addition during the calculation procedure, it is partly necessary to make assumptions and simplifications, and therefore DSD results are very sensitive to the calculation parameters which are set by the manufacturer or which can be set by the user of the equipment.

The most common techniques for DSD measurement are presented in Table 1 which shows the measuring principle as well as the analyzable drop size range and some restrictions of the method.

Progress in the field of emulsions has evolved complex structures, like multiple emulsions (Muscholik 2007; Jiménez-Colmenero 2013). As in a multiple emulsion, there are more than one DSD to determine the complex structure that challenges the common measuring techniques. However, progress in the field of DSD determination of double emulsions has been made. Especially PFG-NMR and IA of confocal laser scanning microscopy images offer possibilities for the characterization of double emulsions (Schuster et al. 2012).

Another important issue in the context of DSD measurements is the illustration and interpretation. DSDs are statistical distributions and can be shown as cumulative or density distributions. Especially showing the latter, it is very important to consider all the rules of their calculation. To the authors' knowledge, there are many measurement devices with very weak software concerning this point. For simplification and interpretation of results, it is very common to show only mean values of the DSD as, e.g., the Sauter Mean Diameter or statistical values like the median or modal value. Some insights on this topic are given in (Hess 2004; Sommer 2001).

Emulsions' Drop Size Distribution, Measurement of, Table 1 Overview on the most important measurement techniques for drop size analytics in emulsions

Method	Physical characteristic for size measurement	Size range	Additional information
Sedimentation	Sedimentation velocity of a single drop	(50 nm) 1 μm –1 mm	Range for the use of centrifuges in brackets. For small drops, very high dilution necessary
(Statistical) image analytics (IA)	Projected area	(0,1 nm) 1 μm –20 mm	Size range depending on the image source. Electron microscopy in brackets. Information on structure and double emulsion detection possible. High number of drops necessary for reliable statistical analysis
Laser diffraction (LD)	Diffraction of light at the drop surface	(50 nm) 1 μm –2 mm	In brackets: with additional light sources and scattering information, necessity of complex refraction index. High dilution necessary
Dynamic laser light scattering (DLS)	Diffusion rate	1 nm–1 μm	Dispersed phase content up to 10 % possible. Drop sedimentation leads to measurement error
Pulsed field gradient nuclear magnetic resonance (PFG-NMR)	Coefficient of diffusion	0,2–100 μm	Measurement without dilution possible. Characterization of some parameters of double emulsions

process of a particular enantiomer from a racemic mixture. The most popular reaction using the technique is esterification, where *Candida rugosa* lipase or *Candida antarctica* lipase is the biocatalyst for the reaction (Giorno et al. 2007; Lau et al. 2010). The application of membranes, especially in the production of drugs and other fine chemicals, has become a trend in recent years and it will be one of the best techniques for the bulk synthesis of such compounds (Lau et al. 2010; Li et al. 2003). Hollow fiber membrane with a particular molecular weight cutoff is the best choice to use as the immobilization matrix.

Enantioselective Membrane

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantioselective membrane is a type of membrane immobilized with a particular catalyst (mainly enzyme) onto the shell side for the purpose of carrying out an in situ reaction-separation

Enantiomer Discrimination (Enantioselectivity)

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantiomer discrimination (or chiral discrimination) is a method used to distinguish between two enantiomers for the purpose of separating the compounds. The term is also related to enantioselectivity where it refers to the discrimination of a given reactant A when it reacts with two alternative reactants B and C or in two different ways (probably at two different sites) with a reactant B (McNaught and Wilkinson 1997). A number of methods have been established to undergo enantiomer discrimination; these include mass spectroscopy (Czerwenka and Lindner 2004; Czerwenka et al. 2004), nuclear magnetic resonance (NMR) (Gafni et al. 1998; Molabaasi and Talebpour 2011), and crystal recognition (Ballesteros et al. 1995; Huai et al. 2006; Klaholz et al. 2000). These methods have been specifically developed based on a particular compound with its own characteristics of crystal structure.

Enantiomers

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantiomers are types of stereoisomer whose structures are mirror image of each other, and they are not superimposable. The property is special to most chiral compounds and exists both naturally or from a particular chemical synthesis (Solomons and Fryhle 2004). It represents the intrinsic property of the building block of life, which consists of amino acids, sugars, peptides, proteins, and polysaccharides (Maier et al. 2001). The simplest compound that exhibits enantiomeric property is 2-butanol with the structural formulae given in Fig. 1.

The existence of enantiomers of a particular compound can be determined when there is a molecule containing one tetrahedral atom with four different groups attached to it, as shown in the two structures of 2-butanol above (McMurry

Enantiomers, Fig. 1 Structural formula of 2-butanol showing two different enantiomers

2004). Specialized drugs are mainly made of compounds that exhibit enantiomeric properties; these include (*S*)-ibuprofen, (*S*)-naproxen, (*S*)-citalopram, and (+)-norcisapride. As can be apparently seen, only one type of enantiomer acts as an active compound compared to their corresponding structures. This shows that the syntheses of such drugs are somewhat important, in particular, for use in pharmaceutical and medical sectors. Some of the processes carried out to obtain the compounds are tedious and require a number of reagents as well as different catalysts. This will then lead to high cost of production (Maier et al. 2001; Tramper 1996).

Enantiomers Production by Membrane Operations

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantiomer production is a process of forming enantiomer of interest through membrane separation. The current method of kinetic resolution and in situ membrane separation is a highly effective process which requires less energy and short reaction time (Lau et al. 2011). Most of the works related to product separations involved lipase enzyme immobilized onto the membrane matrices. These include the production of naproxen ester (Giorno et al. 2003, 2007) and ibuprofen ester (Lau et al. 2010).

Enantiomers Separation by Membrane Operations

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantiomers separation is a process of separating isomers in a racemic mixture into their individual enantiomer. The use of membranes in chiral separation can be divided into two main categories, namely, adsorption-type enantioselective membranes and membrane-assisted resolution with non-enantioselective solid membranes (Pirkle and Bowen 1994; Xie et al. 2008). The former is entirely based on the transport mechanism with an aid of chiral carriers. The work of Gumi and co-workers reported a detail account of the transfer of the (*S*)-propranolol attached to the N-hexadecyl-L-hydroxyproline through the formation of ionic pair, which is then being transported through the polysulfone-based membrane (Gumi et al. 2005). The latter is a technique mostly coupled with enzymes as biocatalysts. The enzyme is initially immobilized onto the shell side of the membrane matrix before carrying out the required resolution,

either kinetic resolution or dynamic kinetic resolution. For example, the work of Long and co-workers successfully utilized *Candida rugosa* lipase as the source of biocatalyst for the kinetic resolution of (*S*)-ibuprofen ester (Long et al. 2005).

Enantioselective Membrane

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantioselective membrane is a type of membrane used to separate chiral compounds into their individual enantiomer. The usual type of membrane used for separation purposes is of polymeric type (Ceynowa 1998; Higuchi et al. 2010; Xie et al. 2008). The mechanism of chiral separation can be categorized into two different types of membranes, namely, diffusion-selective membranes and sorption-selective membranes. Diffusion-selective type of membranes are basically made of polymer without any specific chiral selectors (i.e., the polymer itself has chiral properties); however, sorption-selective membranes can be designed in such a way that a particular chiral selector can be immobilized onto the surfaces of the polymer membranes, which later gives less selective

diffusion, but provides highly selective sorption (Hadik et al. 2002; Higuchi et al. 2010).

Enantioselective Separations, Membrane Operations

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantioselective separations refer to separation methods used to separate racemic mixture into individual enantiomer with the aid of membrane matrix/module. In order to measure the level of selectivity, the percent enantiomeric excess (% ee) of a mixture needs to be determined (see enantioselectivity). Membranes have been successfully used in chiral separation with various types as well as with different abilities: direct separation type of membrane made from polymer/liquid and separation with nonselective membrane assisted by chiral carriers/support (Maier et al. 2001; Pirkle and Bowen 1994).

Enantioselective Synthesis

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Nibong Tebal, Penang, Malaysia

Enantioselective synthesis is a chemical/biochemical reaction where only one enantiomer of a chiral product is preferentially formed. The synthesis can be divided into two different types, namely, catalytic synthesis and biocatalytic transformation. Nowadays, chemical catalysis has been continuously improved, especially in terms of yields and percentage enantiomeric excesses (%e.e), for instance, the synthesis of spirocyclic oxindolo- β -lactam, a combination of indole and β -lactam, which acts as antibacterial, antiviral, and antifungal agents (Zhang et al. 2014). The structure of spirocyclic oxindolo- β -lactam or commercially known as chartelines is given in Fig. 1.

Zhang and coworkers reported that the construction of chartelines started from the bifunctional N-heterocyclic carbene undergoing Staudinger reaction of ketenes with isatin-derived ketimines. For such a highly complex compound, the %e.e reached up to 95 % with the yield of 89 %. Similar goes to the synthesis of γ -, δ -, and ϵ -chiral-1-alcoids, reported by Xu and coworkers (2014). The reaction was based on

both chemical and biological catalyses utilizing Zr for the carboalumination reaction and later applying lipase originated from *Pseudomonas cepacia* for the acetylation reaction. However, by comparing both types of reactions, biocatalysis has been known to provide better yield as well as %e.e (Tsai and Dordick 1996). One of the recent works in the development of pharmaceutically active compounds has been reported by Wen and colleagues where the group managed to synthesize (*S*)-propranolol through a coupled reaction with kinetic resolution as a recycling route utilizing *Candida antarctica* lipase B. The result showed an improve %e.e up to 100 % (Wen et al. 2014).

Enantioselective Synthesis by Membrane Operations

Mohamad Hekarl Uzir

School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantioselective synthesis by membrane operations refers to chemical reactions to produce one enantiomer from a racemic mixture utilizing

membrane as a medium of separation. The process occurs in situ, where the product formed from the reaction will be directly separated into the required enantiomeric compound (Giorno et al. 1995; Long et al. 2005). Another enantiomeric synthesis, which applied the hollow-fiber membrane module, is from the work of Hadik and co-workers. The polymeric membrane made from polypropylene was used together with a chiral selector, N-3,5-dinitrobenzoyl-L-alanine octylester, initially dissolved in toluene (Hadik et al. 2002). Hollow-fiber membrane has also been applied with different types of chiral selectors for large-scale separation processes. The reported results suggested that N(1-naphthyl)-leucine provided a wide range of enantiomeric separation of amino acid derivatives with %ee of up to 95 % (Pirkle and Bowen 1994).

Enantioselective Transport of Amino Acids by Membrane Operations

Keiji Sakaki

National Institute of Advanced Industrial Science and Technology (AIST), Research Institute for Sustainable Chemistry, Tsukuba, Ibaraki, Japan

Amino acids are molecules that contain an amino group ($-\text{NH}_2$), a carboxylic acid group ($-\text{COOH}$), and a side chain in each structure and

are the structural units of proteins. The most of amino acids found in nature are categorized as α -amino acid in which the amino group is attached to the carbon atom adjacent to the carboxylic acid group. An α -amino acid can exist in either of two optical isomers except glycine, and the isomer is normally described as L- or D-amino acid. The majority of amino acids in living organisms are L-isomers. Optical isomers, including amino acids, frequently show different bioactivity from each other. So, optical resolution of amino acids has been an important subject in various industries dealing with pharmaceuticals, foods, agrochemicals, and so on.

Optical resolution with membrane processes has potential merits over other separation methods like crystallization or chromatography. Membrane operation can be carried out continuously and it enables the large-scale separation. Optical resolution of amino acids can be achieved by the function of chiral recognition sites of solid membranes and liquid membranes. The method using liquid membranes is described in another site, so solid membranes for enantioselective separation are explained here. A main research topic on enantioselective membranes is the design of the membranes that have the chiral recognition sites. Some enantioselective solid membranes have been reported as follows.

Membranes Prepared from Chiral Polymers

Polypeptide and polysaccharide, like cellulose, alginate, and chitosan, and their derivatives are chiral polymers, and membranes from these chiral polymers have been applied to the enantioselective separation of racemic amino acids. The separation factor of these membranes toward racemic tryptophan is usually in the range of 1.1–5.0 (Higuchi et al. 2010). Membranes prepared from polymers with chiral branch have been also reported.

Membranes Added with Chiral Selectors

Enantioselective membranes can be prepared by the addition of chiral selectors that show

enantioselective affinity toward amino acids. Cyclodextrins, bovine serum albumin (BSA), and DNA have been used as chiral selectors. The membranes added with these chiral selectors showed the separation factor of 1.1–2.7 toward amino acids (Higuchi et al. 2010).

Molecular Imprinting Membranes (MIMs)

Molecular imprinting membranes are fabricated by incorporating the template molecules into the membranes and then removing the template molecules. The formed cavities in the membranes show the specific affinity with the template molecules and their analogue (Yoshikawa et al. 1995). Although MIMs currently show low enantioselectivity, this method has the potential of higher enantioselectivity (Xie et al. 2008).

Solid enantioselective membranes can be divided into two classes: diffusion-selective membranes and sorption-selective membranes (van der Ent et al. 2001; Xie et al. 2008). A diffusion-selective membrane is defined as a membrane with no specific chiral selectors for the chiral interaction but consists of a chiral polymer. Diffusion selectivity is caused by the chiral discrimination during diffusion. On the other hand, in a sorption-selective membrane, chiral selectors are embedded in a polymer matrix. To reach permeation selectivity in sorption-selective membranes, the selectively adsorbed population has to be mobile. An electrical potential is sometimes used for the purpose.

Enantioselectivity

Mohamad Hekarl Uzir
School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantioselectivity is the preferential formation of a chemical reaction (mainly with metal complexes catalysts) of one enantiomer compound over the other (McNaught and Wilkinson 1997). The extent of enantiomeric reactions is determined by the percentage enantiomeric excess (% *e.e*) given by;

$$\% e.e = \frac{S - R}{S + R} \times 100$$

References

- McNaught AD, Wilkinson A (Eds.), (1997) IUPAC - Compendium of Chemical Terminology, Blackwell Science Ltd., Oxford, England, UK

Enantiospecificity

Mohamad Hekarl Uzir
School of Chemical Engineering, Universiti Sains Malaysia, Penang, Malaysia

Enantiospecificity is the ability of an enzyme to convert a racemic mixture into a particular enantiomer. The degree of specificity is interrelated with that of selectivity, which equation suggested by Lopez and coworkers (Lopez et al. 1990):

$$E_o = E^2 \left[\frac{\tanh(\Phi/E^{0.5})^{-1} - (E^{0.5}/\Phi)}{\tanh(\Phi)^{-1} - \Phi^{-1}} \right]^2$$

where

$$E = \frac{\ln[1 - c(1 + ee_p)]}{\ln[1 - c(1 - ee_p)]}$$

and

$$\Phi = \frac{v_{obs}}{D_{eff}S_o} \left(\frac{R}{3}\right)^2$$

and c is the conversion of the particular reaction (Tsai and Dordick 1996). If the calculated intrinsic enantioselectivity is extremely high, therefore, the reaction can be considered as enantiospecific.

Encapsulation

Goran T. Vladislavljević and Richard G. Holdich
Department of Chemical Engineering,
Loughborough University, Loughborough,
Leicestershire, UK

Synonyms

Encapsulation: [entrapping](#), [enclosing](#), [enveloping](#);
Amphiphilic substances: [Amphiphiles](#)

Definitions

Encapsulation: Coating or entrapping of active ingredient inside a solid shell or within a liquid or solid matrix of another material.

Complex coacervation: Coacervation caused by the interaction of two oppositely charged macromolecules.

Internal phase separation: Phase separation within emulsion droplets consisted of a mixture of polymer, good solvent and poor solvent, usually triggered by removal of good solvent.

Micelles: Spherical aggregates of surfactant molecules dispersed in an aqueous solution.

Liposomes: Spherical vesicles whose shells consist of single or multiple concentric bilayers resulting from the self-assembly of phospholipids in an aqueous solution.

Colloidosomes: Spherical vesicles whose shells consist of coagulated or fused colloid particles.

Polymersomes: Spherical vesicles whose shells consist of amphiphilic block copolymers.

Amphiphilic molecules: Surface active molecules made up of two parts, a polar or electrically charged hydrophilic part and a hydrophobic part, most often an alkyl chain.

Polycondensation: A polymerization in which the growth of polymer chains proceeds by condensation reactions between molecules of all degrees of polymerization.

Layer-by-layer polyelectrolyte deposition: A thin film fabrication technique based on depositing alternating layers of oppositely charged polyelectrolytes with wash steps in between.

Encapsulation is a process of enclosing or entrapping a core material (liquid, gas, solid particles, cells, dissolved active ingredients, etc.) inside a solid shell or within a solid or liquid matrix for the purpose of controlled or triggered release, immobilization, isolation, or protection of the encapsulated material. The material being encapsulated is called the core material, and the carrier material used for envelopment or entrapment is called the shell material. Typical examples of core materials are ink or dye for carbonless copy papers, liquid crystals for microparticle-based displays, phase-change material for smart textiles, high-molecular-weight gases for ultrasound contrast imaging, genetic material for in vitro compartmentalization, active food ingredients for functional food products, enzymes for biocatalytic reactors, drugs, pesticides, fragrances, antimicrobial agents, etc.

Encapsulation, Fig. 1 Schematic diagrams of capsules with different morphologies

Encapsulation efficiency (EE) is defined as the percentage of core material incorporated into the microcapsules relative to the total amount of the core material added during encapsulation process: $EE = (m_E/m_T) \cdot 100 \%$, where m_E is the mass of the core material incorporated and m_T is the total mass of the core material added. Loading capacity refers to the percentage of core material incorporated within the microcapsules relative to the total mass of the microcapsules (i.e., core + shell material).

Two main types of capsules can be distinguished, core/shell (reservoir) type and matrix type. In the core/shell capsule (Fig. 1a), the shell material completely surrounds and contains an internal core material (the internal phase). The strategies used for formation of shell are spray coating, complex coacervation, polymer precipitation by internal phase separation, interfacial reaction that may include polycondensation or cross-linking, and layer-by-layer polyelectrolyte deposition (Yow and Routh 2006). The core material can be released from core/shell capsules by simple molecular diffusion through the shell or by

deliberately compromising the integrity of the shell, e.g., by exposing the microcapsule to environmental stresses such as mechanical forces, change of pH, temperature, or ionic strength, or by chemical or biochemical degradation of the shell. A special class of core/shell capsules are micelles and vesicles (liposomes, polymersomes, and colloidosomes), formed by self-assembly of amphiphilic molecules (phospholipids and diblock copolymers) or particles (Dinsmore et al. 2002). Micelles are formed spontaneously when amphiphiles are dispersed in a polar solvent at concentrations that exceed a critical level, known as the “critical micelle concentration” (CMC). Micelles containing solubilized materials are referred to as microemulsions. A difference between micelles and vesicles is that vesicles are not a thermodynamically stable state of amphiphiles and do not form spontaneously, e.g., without input of external energy (Tadros 1993).

In the matrix-type capsule (Fig. 1b) the core material is distributed uniformly throughout a matrix of shell material. The most common release pattern from matrix-type capsules is first order in which the release rate decreases exponentially with time until the active ingredient is exhausted. Typical matrix-type capsules are multiple emulsions, hydrogel particles, solid lipid particles, polymeric particles, etc. Hybrid structures consisting of a number of hierarchically assembled homogenous phases may be engineered that allow for even finer control over the functionality of microcapsules (Fig. 1c, d).

Synonyms

Bichromal particles synonym: Two-colored particles;
Microencapsulation synonym: Microentrapment

Definitions

Carbonless Copy Paper - Paper coated on the back side with colorless dye or ink capsules, that burst under the pressure of writing or typing and react with colorless clay particles coated on the upper surface of the second sheet.; Phase Change Material - A substance with a high heat of fusion that absorb or release a high amount of energy during melting or freezing, thus acting as a thermal energy storage; Electrophoretic display - a display that forms images by rearranging charged pigment particles with an applied electric field.

Microencapsulation can be done:

1. To protect the encapsulated material against oxidation or deactivation due to reactions with reactive species from the environment.
2. To mask the organoleptic properties like color, taste, and odor of the actives.
3. To achieve controlled/triggered/targeted release.
4. For safe handling of toxic materials.
5. To achieve in vitro compartmentalization or immobilization of biological materials and catalysts.

Microencapsulated materials are utilized in agriculture, pharmaceuticals, foods, cosmetics

and fragrances, textiles, paper, paints, coatings and adhesives, toner applications, and many other industries.

Carbonless copy paper developed by Green and Schleicher in the 1950s was the first commercial product to employ microcapsules. A coating of microencapsulated colorless ink is applied to the top sheet of the paper, and a developer is applied to the subsequent sheet. When pressure is applied by writing, the capsules break and the ink reacts with the developer to produce the dark color of the copy. Paper-like displays with low power consumption such as rotating bichromal microspheres system and microencapsulated electrophoretic system are other examples of commercial applications of microencapsulated ink (Yoshizawa 2004). In the rotating bichromal system (Gyricon), bichromal capsules with oppositely charged hemispheres are free to rotate within oil-filled cavities. In the microencapsulated electrophoretic display system (E ink), oppositely charged black and white particles move under an applied electric field in a clear liquid encapsulated within a transparent capsule.

Today's textile industry makes use of microencapsulated materials to enhance the properties of finished goods. One application increasingly utilized is the incorporation of microencapsulated phase change materials (PCMs), such as paraffin wax. Phase change materials absorb and release heat in response to changes in environmental temperatures. When temperatures rise, the phase change material melts, absorbing excess heat, and feels cool. Conversely, as temperatures fall, the PCM releases heat as it solidifies, and feels warm. Microencapsulation is also used in thermochromic and photochromic fabrics, which change color with changes in temperature or light, insect-repellent fabrics, which ward off mosquitoes, and scented fabrics, which release fragrance (Nelson 2002).

Pesticides are encapsulated to be released over time, allowing farmers to apply the pesticides less often rather than requiring very highly concentrated and perhaps toxic initial applications

followed by repeated applications to combat the loss of efficacy due to leaching, evaporation, and degradation.

Ingredients in foods are encapsulated for several reasons (Gouin 2004). Most flavorings are volatile; therefore, encapsulation of these components extends the shelf life of products by retaining the food flavors within that would otherwise evaporate out and be lost. Some ingredients are encapsulated to mask taste, such as nutrients added to fortify a product without compromising the product's intended taste. Alternatively, flavors are sometimes encapsulated to last longer, as in chewing gum. Some food ingredients must be encapsulated to be protected from oxidation or other degradation reactions caused by exposure to light, moisture, or oxygen. Microencapsulation preserves lactic acid bacteria, both starters and probiotics, in food and during the passage through the gastrointestinal tract, and may contribute to the development of new functional foods.

Many drug formulations for oral, intravenous, ocular, and subcutaneous administration are microencapsulated to achieve controlled, targeted, or triggered release of active ingredients. Aspirin, for example, can cause peptic ulcers and bleeding if doses are introduced all at once.

Microencapsulation of cells and enzymes is used to improve efficiency of bioreactors since very high volumetric productivity can be achieved; encapsulated biocatalysts typically have greater thermal and operational stability and downstream processing is simplified, since the encapsulated biocatalyst can easily be recovered and reused. In molecular biology, single-cell encapsulation is used to achieve high-throughput screening in directed evolution experiments.

Encapsulation Efficiency

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The encapsulation efficiency (EE%) is defined by the concentration of the incorporated material (such as active ingredients, drugs, fragrances, proteins, pesticides, antimicrobial agents, etc.) detected in the formulation over the initial concentration used to make the formulation.

Encapsulation efficiency (EE %) was calculated using below formula:

$$EE \% = (W_t/W_i) \times 100\%$$

where W_t is the total amount of the incorporated material and W_i is the total quantity of incorporated material added initially during the preparation. W_t and W_i can be determined using spectroscopic or chromatographic method. If the capsule shell material is a polymer, it can be dissolved in the solvent, and the incorporated molecule will get soluble and it can be quantified. If the incorporated molecule is not soluble in that solvent, it can be extracted by adding the capsules in a liquid in which the target molecule is soluble (also by multiple extraction). If the core material is a liquid (such as emulsions), the amount of the encapsulated material can be evaluated after induced separation of the liquid dispersed phase and liquid continuous phase (i.e., simple emulsions) or in the outer liquid phase (i.e., W_2 in water-in-oil-in-water ($W_1/O/W_2$) emulsions). The amount of water retained within the oil droplets during emulsification is also significant for double emulsion. The methods used in this particular case enclose the measure of the outer water phase conductivity by differential scanning calorimetry (DSC) (Schuch et al. 2013).

The encapsulation efficiency can be influenced by (i) the partition coefficient of the target molecule in the solvents used in the preparation of the formulation, (ii) the method used to carry out the

encapsulation process (temperature, pH, mechanical stress), and (iii) the size distribution of the capsules (Jyothi et al. 2010).

Encapsulation Techniques

Goran T. Vladislavljevic
Department of Chemical Engineering,
Loughborough University, Loughborough,
Leicestershire, UK

The encapsulation technique of choice depends on the type and physical properties of the core and shell material. The chosen encapsulation technique should give a high encapsulation efficiency and loading capacity of actives, capsules should not exhibit aggregation or adherence, capsules should have a narrow particle size distribution without tails, threads, or dents on the surface, and the process should be suitable for industrial scale production.

Depending on the initial physical state of the core phase, two different fabrication routes can be distinguished: (i) coating solid particles by shell-forming material in a fluidized bed or pan coater and (ii) dispersing a capsule-forming material in the form of droplets in another immiscible liquid or air, followed by droplet solidification. There is a variety of atomization and dripping processes by which a liquid phase can be dispersed in another immiscible fluid (Table 1).

Depending on the chemical composition of the shell-forming material, solidification of air suspended droplets can be achieved by solvent

Encapsulation Techniques, Table 1 Classification of dispersion techniques used in encapsulation processes

Liquid/air dispersion	Liquid/liquid dispersion
Atomization	Emulsification
Pressure nozzle	High pressure homogenizers
Two-fluid nozzle	Ultrasound homogenizers

Wurster process	Internal phase separation	

evaporation, cooling, or cross-linking in a hardening bath. Emulsification routes involve emulsification of a solution or suspension of actives, followed by shell/matrix formation by internal gelation, polymerization, layer-by-layer electrostatic deposition, internal phase separation, coacervation, etc. (Table 2).

Hydrogel capsules contain a hydrophilic active entrapped within a hydrophilic polymer network

that can absorb and hold large amount of water. A gel network can be formed by chemical gelation (polymerization by free radical processes or via condensation) or by physical gelation, which can involve heating (heat-setting gels), cooling (cold-setting gels), or the addition of multivalent counterions (ionotropic gelation). In the internal ionotropic gelation, the droplets of W/O emulsion contain a gel-forming polymer (e.g., alginate) and a cross-linking agent in a nondissociated form (e.g., calcium carbonate), whereas the continuous oil phase contains a species (e.g., hydrogen ions) that diffuses into the droplets and triggers the release of cross-linking agent in its active form and subsequent gelation. In the external ionotropic gelation, the droplets initially contain only a gel-forming polymer, and cross-linking occurs in a hardening bath (Zhang et al. 2007).

Coacervation involves the phase separation of one or more polymers from the initial solution and the subsequent deposition of the newly formed coacervate phase around the active ingredient suspended or emulsified in the same reaction media. In simple coacervation, phase separation is achieved by addition of desolvating agent (alcohol or salt) or by change in temperature or pH, whereas complex coacervation involves reaction between two oppositely charged polymers. The three basic steps in coacervation are (i) phase separation in a suspension or emulsion of active ingredient which leads to a three-phase system consisting of a polymer-rich liquid phase (coacervate phase), a polymer-lean liquid, and a solid or liquid phase containing active ingredient; (ii) deposition of the coacervate phase onto the dispersed particles or droplets; and (iii) hardening of the coating (Zuidam and Shimoni 2010).

Solid lipid microparticles contain the active ingredient entrapped within a high melting point lipid, such as fatty alcohols, fatty acids, fatty acid esters of glycerol, hydrogenated fatty acid esters, waxes, etc. Solid lipid microparticles can be fabricated by a temperature-controlled emulsification of high melting point lipids followed by cooling or by emulsification/solvent evaporation method. In the latter case, a high melting point lipid is dissolved in an organic solvent, and the mixture

is emulsified with an aqueous phase at room temperature. The solid particles are then formed by evaporation of the organic solvent. Hydrophilic actives can be encapsulated by forming a W/O/W emulsion prior to solvent evaporation or cooling (Jaspart et al. 2005).

Liposomes are usually prepared using two approaches: (i) hydration of dry lipid films with an aqueous solution of actives resulting in formation of large multilamellar vesicles (MLV), which is then followed by size reduction of MLVs by sonication, microfluidization, repetitive freezing and thawing, or extrusion through track-etch polycarbonate membranes, and (ii) mixing a nonaqueous lipid solution with an aqueous solution (Walde and Ichikawa 2001).

Enhanced Oil Recovery (EOR)

Arnaud Baudot

Physics and Analysis Division, IFP Energies
Nouvelles, Solaize, France

Enhanced oil recovery (EOR) aims at increasing the oil field's recovery yield, thanks to high-pressure injection of water or carbon dioxide. Injection of pressurized carbon dioxide leads to the maintenance of high pressures in the reservoir and to an improvement of oil displacement, thanks to several physical effects: decrease of oil viscosity due to carbon dioxide solubilization, stripping effects, and modification of multiphase equilibria due to CO₂ solubilization in the reservoir aqueous phase. When the oil reaches the surface, carbon dioxide is purged with the associated gas. Since the volumes of concerned carbon dioxide are very large – from 140 to 280 Nm³ par extracted barrel (Mazur and Chan 1982) – it is necessary to separate carbon dioxide from the

hydrocarbon gaseous phase in order to have it recycled to the reservoir (after pressurization).

Since the quantity of CO₂ dissolved in oil varies over a large range of values during the whole production of the reservoir (levels from 40 % up to 90 % can be observed after a few years of production (Cooley and Dethloff 1985)), it is rather difficult to design a cost-effective CO₂ removal unit that could operate during the entire life of the reservoir. Therefore, modular CO₂ removal units such as membrane operations offer much flexibility for such an operation (Table 1).

The first large-scale EOR project operating membranes has been carried out in the Sacroc oil field located in Western Texas. Carbon dioxide injection was launched in 1972 (at a flow range up to 240,000 Nm³/h). Three CO₂ recovery units were initially installed: two hot potassium carbonate-based absorption units (operated by Sun Explo with a 190,000 Nm³/h capacity leading to a reduction of carbon dioxide from 24 % to 0.5 % and Chevron, with a 54,000 Nm³/h lowering CO₂ content down to 1 %) and an amine (MEA)-based absorption unit (operated by Monsanto, with a 20,000 Nm³/h capacity). At the end of the 1970s, realizing that the level of CO₂ was raising at a higher rate than expected, Chevron contacted Cynara in order to install and operate two gas permeation units upstream of the hot potassium carbonate absorption columns. The

Enhanced Oil Recovery (EOR), Fig. 1 EOR example of permeation application (Spillman 1989)

treatment capacities of the membrane units were, respectively, 60,000 Nm^3/h at 35 bar feed pressure prior to the Sun unit and 25,000 Nm^3/h at 33 bar feed pressure prior to the Chevron unit. Cynara chose to operate a single-stage configuration, the membrane module being installed in parallel. The membrane operation proved to be highly flexible and reliable, as the membrane modules remained in operation twice longer than the expected lifetime (more than 5 years instead of 2–3 years) without any selectivity decrease. A slight decrease in membrane permeability has nevertheless been observed throughout the operation, and it was necessary to add more modules in order to maintain the production level of the membrane operation (Marquez and Hamaker 1986).

Since then, other membrane companies have seen their products involved in other EOR projects:

- Kvaerner membrane systems (Chapel et al. 1999):
Dallas Production Inc. (Texas) treated 200,000 Nm^3 of gases containing up to 25 % of carbon dioxide in 1994 during a feasibility study that lasted for 18 months. After this test, the membrane unit was in operation treating 1200 Nm^3/h .
Hydrocarbon Operating, Inc. (Texas) processed 590 Nm^3/h at 51 bar feed pressure in 1994 on a pilot skid composed of two tubular membrane modules.

– Medal:

A Medal membrane unit was operated at the need of the 1990s to process 14,200 Nm^3/h at 56 bar, 48 % CO₂, reducing the retentate CO₂ concentration down to 6 %.

– Cynara (Kohl and Nielsen 1995):

Amoco, Texas (1994): Cynara membranes were used to process 35,000 up to 120,000 Nm^3/h of gas containing 80 % CO₂.

Mobil, Salt Creek (1992): Cynara membranes were used to process 76,000 up to 120,000 Nm^3/h of containing 70 % CO₂.

Shell, Texas: Cynara membranes were used to process 13,000 Nm^3/h of gas containing 70 % CO₂ (Fig. 1).

Environmentally Friendly Solvents and Diluents

Zhaoliang Cui

State Key Laboratory of Materials-Oriented Chemical Engineering, College of Chemistry and Chemical Engineering, Nanjing Tech University, Nanjing, China

Non-solvent-induced phase separation (NIPS) and thermally induced phase separation (TIPS) are two major methods for polymeric porous membrane preparation. Solvents and diluents play important roles in NIPS and TIPS processes, respectively, influencing the final membrane properties during polymeric membrane formation. Applicable solvents for the NIPS process are N, N-dimethyl acetamide (DMAc), N,N-dimethyl formamide (DMF), hexamethyl phosphoramide (HMPA), N-methyl pyrrolidone (NMP), tetramethylurea (TMU), triethyl phosphate (TEP), trimethyl phosphate (TMP), acetone (Ac), and tetrahydrofuran (THF), while applicable diluents for the TIPS process are dimethyl phthalate (DMP), diethyl phthalate (DEP), dibutyl phthalate (DBP), dihexyl phthalate (DHP), ethyl acetoacetate (EAA), propylene glycol carbonate (PGC), diphenyl ketone (DPK), diphenyl carbonate (DPC), cyclohexanone, camphor, and butyrolactone. Most of the above solvents/diluents are toxic, making the work atmosphere detrimental for workers and environment. Since

many membrane processes are employed with the objective of environmentally improving the process industry, toxic solvents/diluents reduce their contributions to environmental protection. Thus, finding more environmentally friendly solvents/diluents is becoming an important topic in the membrane preparation field (Cui et al. 2013a).

Recently, efforts have been done to develop environmentally friendly solvents for NIPS process and diluents for TIPS process. These solvents/diluents should yield the membranes' promising properties and performances without discharging toxicity to environment. It is much better if the solvents/diluents can be recovered easily. Dimethyl sulfoxide (DMSO) and glycerin triacetate (GTA), which can be employed for NIPS and TIPS process, are relatively less toxic. They have been used for polymeric membrane preparation. Acetyl tributyl citrate (ATBC) (Cui et al. 2013b), which is more environmentally friendly, was introduced to prepare poly(vinylidene fluoride) (PVDF) membranes via TIPS process. Dimethyl sulfone (DMSO₂) (Liang et al. 2013) was used as a universal crystallizable diluent to fabricate polar polymer membranes (PVDF, polyacrylonitrile (PAN) and cellulose acetate (CA)) via TIPS method. This diluent is easy to recover because of its crystallizable property. The membranes fabricated by above diluents presented promising mechanical properties and water permeability. Ionic liquid is a type of green solvents, which probably can be used for polymeric membrane preparations. CA membranes (Xing et al. 2010) have been formed via phase inversion employing 1-butyl-3-methylimidazolium thiocyanate ([BMIM]SCN) as the solvent and were recycled. The morphology, porosity, and pure water permeability of the CA membranes fabricated by reused solvents were quite comparable to the CA membranes produced by new solvents.

Researchers started to pay attention to develop environmentally friendly solvents/diluents, and preliminary progress has been made. However, this is far from the requirements, and more efforts are needed to contribute to this field.

Enzymatic (Peroxidase) Membrane Bioreactor

María. T. Moreira¹, Gemma Eibes²,
Thelmo Lu-Chau², Roberto Taboada-Puig²,
Adriana Arca-Ramos², Gumersindo Feijoo²,
Juan M. Lema² and Lucia Lloret³

¹Department of Chemical Engineering, School of Engineering, University of Santiago de Compostela, Santiago de Compostela, Spain

²Department of Chemical Engineering, Institute of Technology, University of Santiago de Compostela, Santiago de Compostela, Spain

³Chemical and Environmental Engineering Department, Federico Santa Maria Technical University, Santiago, Chile

Enzymatic (peroxidase) membrane bioreactor is an enzymatic reactor coupled to a membrane in a number of configurations that allows the

separation of the enzyme and its reuse in the enzymatic process.

This technology is especially suitable in continuous operation by ensuring the recovery and reusability of the enzymes, allowing the minimization of large consumptions of biocatalyst. Various enzymatic membrane bioreactor configurations are possible, i.e., enzyme suspended in solution in a reactor connected with a membrane unit, immobilized enzyme within the membrane matrix itself, or entrapped enzyme in gel or microcapsules.

Among these setups, the retention of the enzyme by an ultrafiltration membrane is a very interesting alternative to overcome the washing out of the catalyst with the treated effluent but also to avoid the enzyme immobilization which is usually related with high costs, complex procedures, and loss of enzyme catalytic activity. In this system the enzyme is added into a reactor tank which is coupled with an ultrafiltration membrane to enable the retention of the free enzyme and its recycling back to the reaction vessel. Thereby, by using an enzymatic membrane reactor, it is possible to separate the biocatalyst from products and/or other substrates by a semipermeable membrane that creates a selective physical/chemical barrier (Fig. 1).

This type of bioreactor offers important benefits: high enzyme loads, prolonged enzyme activity, high flow rates, reduced energy requirements, straightforward operation, and scale-up, and also, fresh enzyme can be easily added to maintain constant enzymatic levels. Indeed, this system has been successfully operated for the continuous application of peroxidases (López et al. 2004) and laccases (Lloret et al. 2013). Specifically, peroxidase-based membrane bioreactors were applied for the transformation of various compounds with bioremediation purposes, for example, for the removal of dyes (Orange II) and estrogenic compounds (estrone, estradiol, ethinylestradiol, etc.). Orange II was successfully transformed by manganese peroxidase (MnP) in an enzymatic membrane bioreactor which consisted of a 250-mL stirred tank reactor (López et al. 2004 in Fig. 1) connected to a polyethersulfone synthetic membrane (Prep/

Enzymatic (Peroxidase) Membrane Bioreactor, Fig. 1 Scheme of an enzymatic (peroxidase) membrane reactor

Scale-TFF Millipore) with a molecular weight cutoff of 10 kDa (Lloret et al. 2013 in Fig. 1). Three stock solutions: H_2O_2 (94–312 mM); Mn^{2+} (33 μM), Orange II (0.1 g/L), and organic acid (1 mM); and MnP (7,000 U/L, 125–225 U/L in the tank), were fed into the bioreactor by independent variable speed peristaltic pumps, thus initiating the catalytic cycle of the enzyme. Under the best conditions evaluated, high decolorization yield can be achieved and minimal enzymatic deactivation, rendering an efficiency of 42.5 mg Orange II oxidized per unit consumed of MnP.

The findings obtained with the proposed reactor configuration allow its application as a novel treatment method for contaminated wastewaters. The simplicity of the operation, which mainly relies on the control of H_2O_2 dosage, promotes the peroxidase membrane bioreactor for further scale-up applications. The oxidative potential of the $\text{MnP-H}_2\text{O}_2\text{-Mn}^{2+}$ system appears to be general enough to be applied for the transformation of a wide range of compounds. The main requirement is that the oxidation potential of a particular substrate has to be lower than that provided by the enzymatic cycle, being the main factors affecting the stoichiometry and kinetics of the process the MnP activity, dosage rate of H_2O_2 , and concentration of the target compound.

Enzymatic Membrane Reactor (EMR)

Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

[Enzyme membrane reactor](#)

A general definition of an enzyme membrane reactor (EMR) is a reactor system where a membrane separation is used to keep larger components in the reactor vessel (i.e., enzymes and/or

macromolecular substrates), while low-molecular-weight molecules (i.e., products and/or inhibitors) are allowed to pass freely through the membrane, thus leaving the reactor as permeate (Drioli and Giorno 1999). In this setup, several advantages of immobilized preparations, together with easy recovery of deactivated enzymes and replacement with fresh catalysts are achieved; inhibitors are continuously removed from the reaction vessel. The direct and deep contact between substrates and biocatalysts limits diffusional resistances, while no activity losses due to fixation to the support occur, thus maximizing the activity of the biocatalyst. On the other hand, enzyme stability is not improved.

Both dead-end and continuous stirred tank reactor (CSTR) ultrafiltration cells with flat membranes can be used as enzymatic reactors.

Performance of dead-end units is largely affected by the flow dynamics of the system; in fact, mixing of substrates and catalysts is not fully accomplished, and concentration polarization phenomena strongly limit reactor performance.

Continuous stirred tank reactors have been more widely adopted, both due to the possibility of concentration polarization control and easy modeling of enzyme kinetic behavior.

Assuming complete mixing within the reactor so that enzyme and substrate concentration in the reactor vessel are uniform, and the latter is equal to its value in the permeate, substrate mass balance in molar form can be written as:

$$(S_f - S)/\tau = R(S, P) \quad (1)$$

where

S_f = feed substrate concentration, ML^{-3}

S = substrate concentration, ML^{-3}

τ = reactor time constant, T

R = reaction rate, $\text{MT}^{-1} \text{L}^{-3}$

Product steady state mass balance similarly will be:

$$(P - P_f)/\tau = R(S, P) \quad (2)$$

where

P = product concentration, ML^{-3}

P_f = feed product concentration, ML^{-3}

Assuming that substrate conversion obeys the simple Michaelis-Menten model, substrate steady state mass balance reduces to:

$$XS_f + [X/(1 - X)]K'_M = K E V/Q \quad (3)$$

R being expressed as $K E S/(K'_M + S)$.

$X = (S_f - S)/S_f$ = conversion degree

K'_M = enzyme Michaelis-Menten constant, ML^{-3}

K = enzyme kinetic constant, T^{-1}

E = enzyme concentration, ML^{-3}

V = reaction volume, L^3

Q = flow rate, $\text{L}^3 \text{T}^{-1}$

The equation in this form is a useful tool to estimate parameters of reaction kinetics. Instead of performing nonlinear parameters estimation procedures, the functional dependence of XS_f on $X/(1 - X)$ can be plotted. The plot should look like a straight line whose slope is $(-K'_M)$ and whose intersection with the XS_f axis is given by the point of coordinate $(V_{\max}\tau)$.

Enzyme activity is usually not constant with time. Physicochemical changes in enzyme structure, thermal denaturation, and microbial contamination cause enzyme activity to continuously decrease with time. When enzymes or cells are compartmentalized in UF cells, biocatalyst losses can even occur due to the wrong choice of membrane molecular weight cutoff. It is conventional to measure the enzyme stability in terms of its half-life time ($t_{1/2}$), that is, the time at which enzyme activity is reduced to half its initial value. It can be calculated from the following equations:

$$K_d = \frac{2.303}{\vartheta} \log \frac{A_{E_0}}{A_{E_\vartheta}} t_{1/2} = \frac{0.693}{K_d} \quad (4)$$

K_d = enzyme deactivation constant, T^{-1}

ϑ = operation time, T

A_{E_0} = initial enzyme activity, or product mass per unit time and reaction volume, M T^{-1}

A_{E_ϑ} = enzyme activity at time ϑ , M T^{-1}

Since biotransformations by means of enzymes are continuous processes, as long as the reactor working life is longer than the native enzyme half-life, enzyme activity decay with time must be taken into account in order to correctly assess reactor performance. A transient substrate mass balance on the CST reactor leads to the equation

$$V[dS(t)/dt] = Q[S_f - S(t)] - V_{\max}V \quad (5)$$

where

V = reaction volume, L^3

S = substrate concentration, ML^{-3}

S_f = feed substrate concentration, ML^{-3}

$V_{\max}$ = enzyme reaction rate at saturating substrate concentration, $ML^{-3}T^{-1}$

Q = flow rate, L^3T^{-1}

Let us assume that substrate inlet concentration is much higher than the enzyme's apparent Michaelis constant, K_M' so that enzyme kinetics is expressed according to zero order kinetics, that is, $R = KE = V_{\max}$. Enzyme activity decay can be expressed in terms of the Arrhenius equation:

$$E = E_0 \exp(-K_d t) \quad (6)$$

where

E = enzyme concentration, ML^{-3}

E_0 = initial enzyme concentration, ML^{-3}

K_d = enzyme deactivation constant, T^{-1}

Equation 5 then takes the form

$$\begin{aligned} [S_f - S(t)]/\tau - dS(t)/dt \\ = V_{\max_0} \exp(-K_d t) \end{aligned} \quad (7)$$

Integration of the differential Equation 7 leads to estimate the outlet substrate concentration:

$$S(t) = \frac{V_{\max_0} [\exp(-t/\tau) - \exp(-K_d t)]}{(1/\tau - K_d) + S_f} \quad (8)$$

Estimation of the deactivation constant can be graphically carried out from Equation 7 plotting

$\ln\{[S_f - S(t)]/\tau - dS(t)/dt\}$ vs t . A straight line is thus obtained whose slope is given by $(-K_d)$ and the line intersects the vertical axis at the point of coordinate $(\ln V_{\max})$.

When the reacting solution is fed to the system, low-molecular-weight products leave the reactor permeating the membrane, whereas enzymes are partially or totally rejected. Then, enzymes tend to accumulate in a thin layer immediately upstream from the membrane causing polarization phenomena to occur. The extent to which concentration polarization affects reactor performance depends on the balance of rejected solutes, e.g., enzymes or cells, accumulation due to membrane rejection and back diffusion to the bulk phase, and eventually on the flow dynamics of the reacting vessel.

For macromolecules (like most biocatalysts), if membrane properties are carefully chosen, membrane rejection is usually very good, while biocatalyst back diffusion towards the bulk phase is extremely slow. The effect of concentration polarization on such reactor performances can then be significant.

Applying the thin film theory to a region immediately upstream from the membrane results in the following steady state mass balance equation:

$$JE = -D_e dE/dx \quad (9)$$

under the boundary condition (BC)

$x \rightarrow \infty E = E_s$

where

J = volumetric flux, $L^3L^{-2}T^{-1}$

E = enzyme concentration, ML^{-3}

E_s = enzyme concentration in the bulk liquid phase, ML^{-3}

D_e = enzyme diffusion coefficient, L^2T^{-1}

Under the assumption of totally rejected enzyme macromolecules, integration of Equation 9 allows one to express the ratio of enzyme concentration in the bulk solution in the presence of concentration polarization to its value in the absence of concentration polarization phenomena as:

$$E_s/E_o = 1/\{(1 - \alpha) + (\alpha/\beta)[\exp(\beta) - 1]\} \quad (10)$$

Enzyme concentration at the membrane–solution interface can thus be related to enzyme concentration in the bulk phase by the following equation:

$$E_w = E_s \exp(\beta) \quad (11)$$

where the dimensionless parameter β is a measure of convective mass transfer, J , relative to the overall mass transfer, D/δ , more generally K_s .

The change of enzyme bulk concentration can be dramatic, with changes in permeate flow rate, and applied pressure. Changes in enzyme bulk concentration may induce a large reduction in reaction rate within the membrane reactor. Under given stirring conditions, therefore, a critical value of flow rate and hence of applied pressure does exist. At flow rates lower than the critical value, the reactor always attains steady operation conditions, and correspondingly outlet product concentration is constant. Beyond the critical value, concentration polarization phenomena promote the localization of a large fraction of enzymes near the membrane surface, seldom leading to an enzymatic gel formation. Correspondingly, an accelerated deactivation of enzyme activity is superimposed on reactor performance thus hindering the attainment of steady state conditions. Experimental evidence suggests that the contribution of polarized enzymes to overall conversion can be negligible, due to the consistency of product concentration in the bulk phase of the reactor and in the permeate.

When macromolecular substrates are involved in the transformation under study, concentration polarization phenomena affect the EMR performance more severely. Diffusion limitations of macromolecular substrates hamper the use of immobilized enzymes in the hydrolysis of high-molecular-weight substrates. By selecting membranes with an appropriate molecular weight cutoff, both enzyme and substrate are retained in an EMR in touch with each other, and hydrolysis

products and/or inhibitors are continuously removed from the system. Soluble enzymes can then act directly on substrate macromolecules without diffusion limitations and steric hindrance imposed by enzyme fixation to a solid support. The stirring features of CST EMRs moreover assures that substrates and/or inhibitors within the reactor vessel are maintained at the lowest possible concentration level. Such reactor configuration is then extremely useful when substrate inhibited reaction patterns are involved or when inhibiting species are assumed to exist in the feed stream.

Diafiltration, semicontinuous, and continuous operational modes can be used.

Operating the reactor in a semicontinuous condition and adding substrate so as to keep its bulk concentration constant leads to meaningful changes in reactor performance as compared to the diafiltration mode. Under both operational mode, permeate flow rate continuously decreases with time.

When EMRs are operated continuously, feeding a slurry of substrate macromolecules to the reactor, concentration polarization phenomena play a dominant role. The presence within the reaction vessel of contaminants or intermediate products, which are not fully hydrolyzed by the enzymatic system under study can lead to membrane fouling or to the formation of a gel layer at the membrane surface. Under such conditions, the filtration rate continuously decreases with time, and it may happen that substrate conversion does not attain steady state conditions. The addition of enzymes capable of hydrolyzing such foulants to low-molecular-weight compounds usually improves reactor performance, eventually approaching steady state conditions in terms of both permeate flow rate and substrate conversion. In addition, antifouling procedures including suitable feed pretreatment or procedures to reduce concentration polarization can be used.

Equation 11 demonstrates the dependence of enzyme concentration at the upstream membrane surface on the flow dynamics of the reaction vessel. Due to the monotonicity of the exponential

function, at given applied pressure operational conditions improving mass transfer in the bulk phase (i.e., increasing axial flow rate improves K_S or D/δ) diminish concentration polarization. High stirring speeds usually improve filtering performance of a CST flat membrane reactor, albeit at the expense of partial enzyme deactivation.

Reactor configurations other than dead end or CSTR/UF cell can offer improvements.

The use of hollow fiber ultrafiltration modules in cross-flow filtration mode strongly improves both reactor performance and economics. Capillary membranes are characterized by a favorable surface to volume ratio; advantages from this feature are not only related to lower overall plant size but also to the increase of the surface to price ratio. Flushing enzyme/substrate solution through UF module tangentially to the membrane surface at a high linear velocity reduces the extent of concentration polarization avoiding the formation of a secondary enzymatic gel membrane. Provided that the volume of the UF module is small relative to the total volume, and that recirculation flow rate is much larger than permeate flux, system kinetic behavior can be modeled in terms of a CST reactor.

Enzymatic Membrane Reactor in Supercritical CO₂

Gilbert M. Rios

Place Eugene Bataillon, IEM – European
Membrane Institute, Montpellier, France

Enzymes are catalysts obtained from nature (proteins), which work in mild conditions and

present very specific activities. They are one of the main tools of life as it developed since the origin. Enzymes are divided into six classes, based on the type of reaction that is catalyzed. Lipases are important enzymes that belong to the class of hydrolases; they catalyze hydrolytic reactions. *Candida antarctica* lipase B (CalB) is one of the most widely used lipases, because this enzyme accepts a broad spectrum of different substrates. Most of the time enzymes are immobilized for industrial applications. The main reason to immobilize enzymes lies in the reduction of costs by enabling efficient separation, recycling, and reuse of the expensive enzymes. The choice for the best immobilization method depends on the enzyme, the type of reaction, and the reaction environment.

The use of porous membrane reactor for enzymatic catalysis represents from this viewpoint a breakthrough technology which offers many advantages as compared to other more classical systems (immobilization on divided solid particles in fixed, fluidized, or moving beds): continuous mode, reduction of product/substrate inhibition, free enzyme end-products, and the possibility to set up monophasic or biphasic systems – even if there can be some drawback related to membrane fouling. The full activity may be maintained inside the reactor by the rejection of enzyme molecules (Fig. 1) either freely circulating (a) or immobilized on/in the membrane (b). In that case, the membrane is the catalyst media (functionalization) and the reaction occurs during membrane crossing. The convective control due to the application of a low transmembrane pressure (very small thickness of the porous layer: a few microns) is responsible for the mass transfer increase. The membrane is a macrosystem resulting from the assembly of swarms of microsystems: each pore represents a particular microreactor.

The main practical use of enzymatic catalysis in supercritical carbon dioxide (scCO₂) has to be found in producing high-added-value products since the process remains expensive. Lipases have proven to be rather stable and active during

Enzymatic Membrane Reactor in Supercritical CO₂, Fig. 1 Basic mechanisms

Enzymatic Membrane Reactor in Supercritical CO₂, Fig. 2 Plant schemas

long-term reactions in scCO₂. However, it cannot be stated that performing reactions in scCO₂ will always result in a higher activity. This is highly dependent on the type of reaction, the enzyme, and the applied conditions. The main advantage of CO₂, a very stable and nontoxic fluid, is therefore

the possibility of easier separation steps with complete removal of the solvent (Fig. 2).

The future perspectives for enzymatic membrane reactors in scCO₂ can be found in the combination of improving the stability and activity of the potentially interesting

enzymes – other types of enzymes are attractive for use in scCO_2 as well, such as oxygenases, epoxide hydrolases, aldolases, or decarboxylases – and an improved integration of the reaction and separation sections. Very interesting studies conducted lately on transesterification reactions with the fixed enzyme configuration (Fig. 1b), either using pure SC fluid solvent containing dissolved substrates or for transforming oils after the injection of a small quantity of pressurized CO_2 in order to decrease viscosity, are worth mentioning.

Enzymatic Ultrafiltration Membranes (Immobilization of Urease and Trypsin)

Christophe Innocent

Institut Européen des Membranes, ENSCM, CNRS, Université de Montpellier, Montpellier, France

The sodium alginate was used as an anionic polyelectrolyte. The polyethyleneimine was used as a cationic polyelectrolyte. Trypsin (enzyme which catalyzed the hydrolysis of peptide bonds in which the carboxyl groups are contributed by the lysine and arginine residues) was applied as a positively charged polyelectrolyte and the urease (enzyme which catalyzes the hydrolysis of urea to ammonium and carbon dioxide) as a negatively charged polyelectrolyte. For adsorption of the polyelectrolyte layers, the supporting membrane (polyacrylonitrile-modified membrane negatively charged) was immersed in the solution of the cationic polyelectrolyte, rinsed with the buffer solution to remove excess of polycations on

Enzymatic Ultrafiltration Membranes (Immobilization of Urease and Trypsin), Fig. 1 Scheme of layer-by-layer adsorption of polyelectrolytes on membrane

membrane surface, immersed in the solution of the anionic polyelectrolyte, and rinsed with the buffer solution again. These steps were repeated to form multiple polyelectrolyte bilayers based on the electrostatic layer-by-layer self-assembly (Fig. 1).

Enzyme Compartmentalization

Rosalinda Mazzei

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

[Immobilization of enzymes](#)

In biology enzyme compartmentalization is efficiently carried out by biomembrane or biological membrane that permits to confine specific functions given by enzymes in a precise space. The enzymes can be localized inside the delimited compartments or on the membrane surface.

In eukaryotic cells the corresponding delimited spaces or compartments are called organelles, from which the main are the endoplasmic reticulum, Golgi apparatus, nucleus, mitochondria, lysosomes, endosomes, and peroxisomes. Each membrane-enclosed organelle contains a specific set of proteins free or on the membrane surface that regulates many vital biochemical processes. For instance, lipid metabolism is catalyzed mostly by membrane-bound enzymes.

Starting from nature simulation, in biotechnology process, enzyme compartmentalization can be obtained by immobilizing proteins on supports or delimiting them by support compartments. Membranes can be optimal supports for enzyme compartmentalization; in fact they are widely

used for the production of membrane bioreactors or biocatalytic membrane reactors (Mazzei et al. 2010). In particular, asymmetric hollow fiber membrane can be used as efficient support to compartmentalize enzymes by entrapment into the sponge membrane layer. The general membrane requirement is that the pores in the dense layer are small enough to retain enzyme molecules and at the same time large enough to freely pass substrates and products (Mazzei et al. 2013).

[Immobilization of enzymes](#)

Enzymes Immobilized on Lumen, Fig. 1 Scheme of tubular biocatalytic membrane with biocatalyst immobilized on lumen surface

This particular kind of immobilization is generally referred to enzymes immobilized into the membrane lumen surface of tubular membranes for the production of biocatalytic membrane and biocatalytic membrane reactors. A scheme of a cross section of a biocatalytic asymmetric hollow fiber membrane is reported in Fig. 1, in which the place that the biocatalyst was immobilized on the membrane lumen surface is highlighted.

The biocatalyst can be also compartmentalized/segregated in the lumen of tubular membrane so confined in a defined region of the membrane module space. In these reactors, the enzymes or cells are not linked to the membrane. The membrane in this particular case can retain the enzyme or the cell which is not lost in the effluent stream, while low-molecular-weight products and inhibitors can be removed through the membrane (Strathmann et al. 2006).

Ethanol Production by Continuous Fermentation-Pervaporation

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Ethanol production by continuous fermentation-pervaporation is a process that couples ethanol fermentation with in situ pervaporation (PV) recovery of ethanol from fermentation broth.

With the fast increasing of fossil fuel consumption and the deterioration of environment, it is commonly accepted that the fossil fuel for human energy use has to be replaced generally by renewable resources. Compared with traditional resources, bioethanol produced by fermentation process can be sustainably developed without extra yield of greenhouse gas (Peng et al. 2011). Bioethanol is produced from renewable resources (biomass) by ethanol fermentation process. However, usually, the maximum concentration of solvents (ethanol) does not exceed 8 wt% owing to the end-product inhibition on microorganism, resulting in high energy cost to separate ethanol from the dilute fermentation broth by distillation. Therefore, several in situ product-removal technologies, such as adsorption, gas stripping, liquid-liquid extraction, perstraction, pervaporation, and reverse osmosis, have been developed. These technologies could be coupled with ethanol fermentation process to decrease the effect of product inhibition and improve the sugar utilization and solvent productivity (Vane 2005).

Pervaporation coupled with fermentation, which is also called fermentation-pervaporation coupled process, has been regarded as the most promising separation method because this process

Ethanol Production by Continuous Fermentation-Pervaporation, Fig. 1 Ethanol fermentation-pervaporation coupled process

can in situ extract organic components which is harmless for microorganisms in mild condition. Figure 1 shows its typical flow chart (Vane 2005). A pervaporation membrane module is connected to the fermentor to form a circulation of fermentation broth. Preheated fermentation solution is continuously circulated from fermentor through the membrane upstream side with another side being vacuumed using vacuum pump. Therefore, ethanol solvent can be selectively and continuously removed from the fermentation broth and then concentrated in the membrane downstream side. As a result, ethanol concentration in the broth is kept at low level to facilitate the continuous fermentation process as well as enhance the solvent productivity. In addition, a microfiltration/ultrafiltration unit can be alternatively installed before the pervaporation module, in order to filter microbes and avoid the biofouling of pervaporation membranes.

PV membranes can be made from either polymeric or inorganic materials, even both of them (Peng et al. 2011). The polymeric pervaporation membranes for extracting ethanol from fermentation broth include polydimethylsiloxane (PDMS) membranes, poly[1-(trimethylsilyl)-1-propyne]

(PTMSP) membranes, poly(ether block amide) (PEBA) membranes, liquid membranes, other modified polymer membranes, as well as porous polypropylene (PP) membranes and polytetrafluoroethylene (PTFE) membranes. Among them, the commonly used PDMS membranes with good selectivity and stability are regarded as the most potential PV membranes for ethanol recovery application (Xiangli et al. 2008). The typical inorganic membrane for PV is hydrophobic zeolite membrane, such as ZSM-5 and Silicalite-1 membrane.

Ethanol–Water Mixtures: Separation by Pervaporation

Kew-Ho Lee

Center for Membranes, Korea Research Institute of Chemical Technology (KRICT), Yuseong-gu, Daejeon, South Korea

Pervaporation is an important membrane process in chemical industries in which valuables are isolated from the liquid mixture. Liquid and vapor separation by thermal processes has always been highly energy intensive, and new separation processes taking advantage of mass transfer through dense membranes have already shown they enable very significant energy savings as compared to more classic technologies (Anne et al. 2002). Membranes can be used for the selective removal of water from aqueous organic mixtures. Pervaporation (PV) is a separation process that involves separation of liquid mixtures, in contact with a membrane. With feed solution on one side, permeate is removed as a vapor from the other side (Brian et al. 2011); pervaporation (PV) is a very well-known membrane process for the separation of liquid and vapor mixtures due to its energetic aspects (EP 909209A1 1999; EP 944575A1 1999; EP 880400A1 1998).

Pervaporation mostly allows a variety of possible application areas: dewatering of organic fluids like alcohols, ketones, ethers, etc. (EP 765682A1 1997); separation of mixtures from narrow boiling temperatures to constant (azeotrope) boiling temperatures (EP 811420A1 1997); removal of organic pollutants from water and air streams (EP 749351A1 1996); separation of fermentation products; and separation of organic-organic liquid mixtures (Kujawski 2000). Pervaporation is also considered as so-called clean technologies, especially well suited for the treatment and recycling of volatile organic compounds and pollution prevention (Anne et al. 2002).

Transport mechanism of PV through polymeric membranes was studied by many research groups, and it was explained by the solution-diffusion model (Binning et al. 1961; Paul and Paciotti 1975; Lee 1975; Mulder and Smolders 1984; Kataoka et al. 1991a, b). According to the solution-diffusion model, each component of the permeation molecules dissolves into the membrane and diffuses through the membrane due to the concentration gradient (Mikihiro et al. 1998) (Fig. 1).

Transport through the membrane is driven by the vapor pressure difference between the feed solution and the permeate vapor. The vapor pressure difference can be maintained by applying a vacuum on the permeate side or by cooling the

permeate vapor so that it condenses, thus creating a partial vacuum. Commercial systems for the dehydration of concentrated alcohol and other solutions have been developed since the 1980s, much of the push coming from interest in the production of pure ethanol as an alternative liquid fuel, where PV can be used to dehydrate (Brian et al. 2011).

Pervaporation Membranes

Polymeric Membranes

For dehydration, where the small molar volume favors the preferential sorption of water, materials have to be selected with a higher affinity for water than for the other component. The polymeric materials can be broadly classified into three categories: glassy polymers, rubbery or elastomeric polymers, and ionic polymers. In general, the glassy and ionic polymers are more suited for making water-selective membranes for dehydration.

For water-selective membranes, the most important factor responsible for the separation is the specific interaction between water and the polymer. To obtain high selectivities, it is

necessary to use polymers, which contain specific groups/active centers, capable of strong interactions with water.

The highest fluxes are those for the hydrophilic membranes based on cellulose and Nafion and grafts of hydrophilic poly(vinylpyrrolidone) on Teflon and polyacrylonitrile. The PVA/TEOS membranes are exceptions in that they are hydrophilic but exhibit low fluxes (Brian et al. 2011) (Table 1).

The emphasis is on selectivity, postulated to be determined by selective sorption and selective diffusion. Selective sorption is governed by the presence in the membrane of active centers such as charged sites which are capable of specific interaction with water, while selective diffusion is governed by the rigidity and regularity of the polymer structure and the nature of the polymer interspace, exemplified by the degree of swelling and the frequency of the cross-links. The results for a series of membranes made by grafting neutral or charged polymers onto supporting membranes are reported in (Table 2).

Polysalts, formed from anionic and cationic polyelectrolytes, would be appropriate for obtaining both highly permeable and highly selective membranes (Semenova et al. 1997) (Table 3).

Ethanol–Water Mixtures: Separation by Pervaporation, Table 2 PV dehydration of 20 % aqueous ethanol at 70 °C using graft polymer membrane having different charges (Brian et al. 2011)

The best performers in terms of flux, which at a maximum of 5 kg/m²h never achieve high values, are charged polymers of one type or another, including polysalts. Anionic and polysalt membranes are superior. For anionic polymers, the proton form has a significantly higher flux than the metal or quaternary ammonium salt versions, owing to the greater free space within the polymer network (Table 4).

Hybrid Membranes

Many a times, the polymeric membranes may fail to meet the desired separation requirements. In such cases, it becomes necessary to add filler materials such as ceramics and zeolites to improve the separation properties of the membrane. There are several reports showing good separation performance for ethanol/water mixture using zeolite membranes (Kita et al. 1995; Sano et al. 1994).

Ethanol–Water Mixtures: Separation by Pervaporation, Table 4 Highest fluxes for PV dehydration of aqueous ethanol (Brian et al. 2011)

	20	50	86	183
	30	50	61	1036

Kita et al. made NaA-type zeolite membrane by hydrothermal synthesis. NaA zeolite membrane is a water-selective membrane, and the PV separation factor of water/ethanol system was over 10,000 at 348 K. For ethanol permselective membranes, Sano et al. (1994) prepared polycrystalline silicalite membrane by the hydrothermal synthesis.

The silicalite membrane showed high ethanol permselectivity, and a separation factor of 58 was realized at 333 K by PV. Silicalite membranes seem to have great potential for the ethanol recovery by PV (Table 5).

Ethyl Cellulose (EC) Membrane

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu
Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Ethyl cellulose (EC) membrane has mainly been used for separation of light gases, such as He, O₂, N₂, CH₄, CO₂, propane, and propylene. The hydroxyl groups on the glucose unit of cellulose

can be substituted with epoxy groups up to about 55 %, where ethyl cellulose exhibits good thin film-forming ability, excellent mechanical properties and durability, outstanding gas separation performance, and cost-effectiveness. Ethyl cellulose can be dissolved in organic solvents (e.g., chloroform) and ethyl cellulose thin film can be formed via solvent evaporation. The “nonporous” ethyl cellulose membrane has been used to separate light gases, where the solubility coefficient and the diffusion coefficient are two major parameters to determine the membrane performance for gas separation. This performance is also influenced by the content of epoxy groups, which vary with different manufacturers (Houde et al. 1997; Li et al. 2001; Ito et al. 1989) (Fig. 1).

Another important application of ethyl cellulose is in film coating of drug tablets. Although the tablet coating does not have a therapeutic value, it does offer the psychological importance in aiding patients to take the medication. The incorporation of color, flavor, and other additives in the ethyl cellulose-coated tablets can improve esthetic and organoleptic values and improve stability and handling capability and drug release properties. For example, ethyl cellulose is a water-insoluble polymer, which can be used to protect the hydrolysis of the drug by surface coating. The drug release rate can be adjusted by varying the thickness of the film and/or the composition of hydrophobic and hydrophilic components in the coating (Sakellariou et al. 1995). Similarly, ethyl cellulose can be used to formulate microcapsules where the target drug(s) can be tailored with controlled release rate, as well as improved efficacy, safety, processibility, and stability (Rogers et al. 2012). It is interesting to note that hydrophobic ethyl cellulose and hydroxypropyl cellulose, which is

Ethyl Cellulose (EC) Membrane, Fig. 1 Etherification of cellulose with maximum content of epoxy of about 55 %

more hydrophilic, are often combined together synergistically for varying biomedical applications (Donbrow et al. 1980).

Ethylene Off-Gas

Paola Bernardo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Ethylene off-gas is a light gas mixture containing various concentrations of ethylene, propylene, hydrogen, methane, ethane, propane, and minor amounts of higher hydrocarbons, nitrogen, and other trace components.

The main ethylene-bearing off-gas streams are produced during the petroleum refining from fluid catalytic cracking (FCC) units and delayed cokers. FCC units alone produce significant amounts of ethylene and hydrogen, owing to the high feed flow rates processed. Other sources for ethylene off-gas streams are the deep catalytic cracking processes.

Refinery and petrochemical ethylene-containing off-gas streams usually contain varying amounts of heavy C_4 – C_{10} hydrocarbons, including alkanes, olefins, and aromatics, together with small quantities of water, nitrogen oxides, carbon monoxide, carbon dioxide, acetylene, methylacetylene, propadiene, butenes, and higher hydrocarbons. FCC off-gases are available at 10–17 bar and typically contain 8–18 vol.% of ethylene, 3–9 vol.% of propylene, and 12–20 vol.% of hydrogen, depending on the FCC feed composition and cracking severity (Netzer 2003). In general, ethylene-bearing off-gas streams contain relatively dilute concentrations of olefins, such as ethylene, with methane, ethane, and hydrogen which are potentially recoverable.

Hydrogen and light hydrocarbons (ethylene, propylene, and LPG) have an increasing worldwide demand. Being more valuable as chemical and plastic feedstocks than they are as fuels, the recovery from off-gas streams of these valuable compounds represents an interesting possibility to increase revenue in refineries (Hoffmann and Kaufmann 2012). Indeed, refinery and petrochemical ethylene off-gas streams are typically burnt in flare stacks or as fuel, since the recovery of the olefins by conventional means, such as fractionation, is considered as not economically viable. Considering the high cost of producing ethylene by thermal cracking of hydrocarbon feedstocks, which is the primary production process for ethylene, the recovery of olefins represents a substantial conservation of resources (Eldridge 1993). The available separation methods are absorption, adsorption, distillation, and membrane separation. Membrane technology represents a cost-effective, flexible, and safe process for recovering ethylene and associated hydrogen from refinery and petrochemical off-gas streams (Ohlrogge et al. 2010).

The use of a membrane system for vapor–gas separation allows valuable feedstocks to be recovered and recycled to the polymerization section in polyethylene and polypropylene production (Baker et al. 1998). Polyolefin plants involve present losses of monomers and other hydrocarbon feedstocks (typically \$1–\$3 million per year in one plant). Vent streams, containing monomer

contaminated with light gases (e.g., N_2 and H_2), are usually flared. Monomer recovery with hydrocarbon-selective rubbery membranes is the largest application of vapor separation membranes. The vent stream is compressed and cooled to condense hydrocarbons. The gas not condensed, still containing a significant amount of hydrocarbons, is sent to the membrane system and separated into a hydrocarbon-enriched stream as permeate and a nitrogen stream. The permeate is recycled to the compressor and then to the condenser where the hydrocarbon is recovered; the nitrogen stream is recycled to the degassing bin (Baker et al. 1998).

Analogous membrane processes are applied to recover ethylene in ethylene oxide and in vinyl acetate production. The purge gas for a typical ethylene oxide plant contains approximately 20–30 % ethylene, 10–12 vol.% argon, 1–10 vol.% carbon dioxide, 1–3 vol.% ethane, 50 vol.% methane, and 4–5 vol.% oxygen. A similar vent gas mixture is produced in the vinyl acetate process. A membrane recovery unit fed with these purge streams will produce an ethylene-enriched permeate stream and an argon-enriched residue stream (Jacobs and Billig 2005). These systems achieve an ethylene recovery greater than 70 %, partly recover methane (the diluent gas), and reduce hydrocarbon burning.

Ethylene Production by Membrane Operations

Paola Bernardo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Ethylene (C_2H_4), also called ethene, is a colorless and flammable gas derived from natural gas and petroleum. Being particularly reactive, ethylene represents one of the largest volume compounds and a key building block in the petrochemical industry, with a worldwide demand that has grown steadily.

The conventional ethylene production process is steam cracking. A hydrocarbon feedstock (such as naphtha, liquefied petroleum gas, ethane, propane, or butane) is thermally cracked in the presence of steam, producing a mixture of hydrogen, methane, ethylene, ethane, and heavier components. Most of the dilution steam and heavier products are condensed by a rapid quenching, while the cooled gases are compressed, sent to a scrubbing for the acid gas removal, and subcooled for the successive separations. A distillation train performs the separation and purification of the gaseous products, representing an energy consuming step, highly heat integrated and requiring refrigeration (Ren et al. 2006). This provides a strong drive for evaluating alternative methods for separation and recovery purposes. Coke formation requires discontinuous operation for reactor cleanup. Different wastes are generated including caustic scrubber effluent, dilution steam condensate, coke and tar at the condensate separators, and vent gases generated during start-ups and shutdowns. Overall, this process is very capital intensive and energy consuming (Ren et al. 2006). This type of hydrocarbon feedstock affects the process capital cost as well as the amounts and types of waste streams. Cleaner and simplified processes are related to the use of ethane. Multiple companies are considering this option, driven by the large volumes of shale gas being recently recovered which provides sizable volumes of very low-cost ethane (Armor 2013).

The integration of membrane separation systems and of membrane contactors (such as membrane distillation, membrane strippers and scrubbers, etc.) and membrane reactors might beneficially contribute to redesign industrial operations. Indeed, membrane technology has many advantages over other conventional technologies, including lower capital and operating costs, low maintenance, low space requirements, flexibility, and ease of installation and operation (Strathmann 2011).

An ethylene production cycle by steam cracking was redesigned by integrating different membrane systems (► [gas separation](#) modules, ► [microfiltration](#), and membrane contactors) into a reference plant producing 800,000 t/year of ethylene and consuming ca. 30 GJ/t ethylene (Bernardo et al. 2004). Membrane gas separation to remove hydrogen from compressed gas allows a debottlenecking, reducing significantly the energy required in the cryogenic distillation for hydrogen/methane separation, permitting less severe operating conditions with respect to the conventional cycle (Engler and Dupuis 2000). Gas separation was also proposed to produce oxygen-enriched air to be used instead of air for combustion and/or decoking. Hydrocarbon removal from water streams using membrane contactors, capable to operate more efficiently with respect to conventional scrubbing units (Gaeta 2009), could achieve a removal greater than 90 %. Membrane contactors could be also applied for acid gas removal from the furnace effluent. Water used for scrubbing of the finest fraction of coke particles during decoking can be processed in a microfiltration membrane unit, recovering up to 90 % of the water and allowing its reuse in the plant. The replacement of traditional operations with membrane units, such as membrane contactors for washing water purification in the “hot section” and the membrane gas separation for the hydrogen recovery, determine a smaller exergetic loss with respect to the conventional industrial cycle (Bernardo et al. 2004).

Membrane reactors with inorganic membranes able to operate at high temperature were investigated for alternative ethylene productions, benefitting from the product continuous removal to shift a chemical equilibrium or from a reactant

continuous feeding to control the reaction selectivity. Some examples, related to the conversion of ethane, include the dehydrogenation by means of hydrogen permeable metallic membranes (Galuszka et al. 2008) and the exothermic oxidative dehydrogenation using perovskite membranes, which operate under a mixed ion-electron conduction (Lobera et al. 2011).

Ethylene/Ethane Separation by Membranes

Paola Bernardo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The separation of ethylene from ethane and propylene from propane is a challenging operation. It is involved in the production of light olefins, such

as ethylene and propylene, which represent the most important building blocks in the petrochemical industry. Cryogenic distillation, conventionally applied to this separation, is highly energy intensive, requiring expensive tall columns, operated under low temperature and high pressure, with very high reflux ratios and requiring ethylene/propylene refrigeration systems for low-temperature cooling (Eldridge 1993).

Due to the complexity and difficulty of the separation process, mixtures including olefins produced in the petroleum and refining process are often used as fuel. Membrane separation, recognized as a low-energy method, appears the most promising among alternative separation techniques, such as extractive distillation, adsorption, and absorption, to recover these valuable compounds (Rungta et al. 2013). Polymeric membranes, cheap and with an easy processability, have low olefin/paraffin separation factor, especially those based on rubbery polymers (Rungta et al. 2013). The experimentally observed ethylene/ethane and propylene/propane upper bound, based on the most reliable data of various polymeric membranes, were presented in two critical reviews (Rungta et al. 2013; Burns and Koros 2003, respectively). Glassy polymers have been studied intensively for this separation. However, when applied to mixtures and/or at high gas activities, these materials are prone to plasticization which causes swelling of the polymer matrix and results in a higher permeability coupled with a loss of selectivity. Strategies to overcome plasticization include thermal curing and chemical cross-linking, which reduce the polymer free volume, and the addition of nanofillers (Goh et al. 2011; Ploegmakers et al. 2013).

Facilitated transport membranes based on the π -complexation mechanism are broadly investigated for olefin/paraffin separation (Faiz and Li 2012). The specific interaction between the hybrid molecular orbitals of the olefins and the atomic orbitals of the transition metals results in reversible chemical bonds stronger than those formed by van der Waals forces, but can be broken by simply increasing the temperature or decreasing the pressure. These systems allow high selectivity for the bound component. Silver-based facilitated

transport membranes were studied more extensively due to low-cost and relatively weak interactions with olefins (possible decomplexation). However, carrier poisoning and short life span of the polymeric membranes are typically reported (Rungta et al. 2013). Chitosan-based membranes, impregnated with silver nitrate as a facilitation agent, showed performance stability over thousands of hours of operation in field tests (Kamza et al. 2013). Ionic liquids, selected as additives for facilitated transport membranes, have a negligible vapor pressure that avoids solvent losses by evaporation and offer more affinity for the olefins compared to the paraffins, providing stability to the metallic cation dissolved inside and acting as a medium for facilitated transport with mobile carrier (Fallanza et al. 2013).

Carbon molecular sieve membranes showed the potential to surpass the polymeric ethylene/ethane upper bound performance (Rungta et al. 2013). These membranes are usually prepared by the pyrolysis of polymeric precursors such as polyimide materials. However, major issues are represented by their brittleness and poor mechanical strength.

In the field of inorganic membranes, metal organic frameworks were recently considered for preparing membranes to be applied to the olefin/paraffin separation (Bux et al. 2011).

The concept of hybrid processes, combining a membrane system with a conventional one, has drawn significant attention for the olefin/paraffin separation. Savings in total costs and energy (up to 30 %) could be obtained with a membrane/distillation hybrid system (Caballero et al. 2009).

Evapomeation (EV)

Tadashi Uragami

Organization for Research and Development of Innovative Science and Technology (ORDIST), Kansai University, Suita, Osaka, Japan

Presently, pervaporation (PV) is applied as the chosen membrane separation technique for the separation of water/organic, organic/water, and organic/organic mixtures. However, it seems that conventional PV is not the most efficient membrane separation process for the treatment of some liquid mixtures as follows. Because the polymer membranes used in PV are directly in contact with the liquid feed solutions as shown in Fig. 1, however, specifically designed chemical and physical properties of the membrane are often impaired by swelling or shrinking of the membrane due to sorption of the feed components. Swelling or shrinking of the polymer membranes is disadvantageous for the membrane performance with respect to the separation of mixtures.

Evapomeation (EV),
Fig. 1 Principle of pervaporation (PV)

Evapomeation (EV),
Fig. 2 Principle of evapomeation (EV)

A novel membrane separation technique known as “evapomeation (EV)” (Uragami et al. 1988; Uragami and Saito 1989; Uragami 1991, 1992, 1993a, b; Uragami 1994; Uragami 1998, 2005, 2006a, b, 2008) makes use of the advantages of PV but reduces the negative effects of swelling on membrane performance. In this technique, the feed solution is fed to the membrane without directly contacting the polymer membrane. This is accomplished by vaporizing the liquid feed so that only vapor is supplied to the polymer membrane as shown in Fig. 2. Therefore, swelling or shrinking of the polymer membranes due to contact with the feed solutions is minimized.

The advantages of EV compared to PV are as follows:

1. In the EV process, membranes are not in direct contact with liquid feed mixtures as only vapors are supplied to the membranes. Accordingly, any swelling or shrinking of the membrane due to the feed mixtures is minimized, and consequently an improvement in membrane performance may be expected.

2. Because the organic liquid mixtures are vaporized, interactions between component molecules are significantly weakened, and consequently the separation performance is remarkably improved.
3. In EV, contaminants in a liquid feed mixture, such as macromolecular solutes, can lead to fouling of the membrane; this problem is avoided in EV.
4. During EV, both temperature of the feed solution and the membrane surroundings can be controlled; hence, an improvement in the permeation and separation characteristics of the membrane can be achieved.

Evaporation Casting

Francesco Galiano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Evaporation casting or dry-casting involves the evaporation of a solvent (or a mix of solvents) from a starting solution and the subsequent formation of a polymeric membrane by precipitation. In this process a polymer is dissolved in a suitable solvent and the solution obtained is spread out across an appropriate support. Then, the solvent is left to evaporate, in inert atmosphere or controlled environment, inducing the polymer precipitation and generating a membrane generally with a dense structure (Fig. 1). In evaporation casting, in fact, the precipitation process is much slower than the precipitation obtained by immersion casting. As a consequence, the membranes present, usually, an isotropic and less porous structure. Some other components, called commonly nonsolvents, can be also added to the initial polymeric solution. In this case, the solvent, the more

Evaporation Casting, Fig. 1 Evaporation casting process

volatile element of the system, will evaporate faster leading to a higher polymer/nonsolvent concentration responsible for the polymer precipitation. The evaporation process can proceed until the membrane has completely formed or it can be stopped by immersing the cast film in a coagulation bath containing a nonsolvent (Baker 2004). By prolonging or reducing the evaporation time before immersion in the coagulation bath, it is possible to tune the pore size of the membrane. When the starting polymeric solution is cast on different support, as porous thin films or other kinds of membranes, an asymmetric membrane with a dense skin layer deposited on a porous support can be obtained.

External Coagulant in Fiber Preparation

Khayet Mohamed

Department of Applied Physics, Universidad Complutense de Madrid, Madrid, Spain

External coagulant is a non-solvent liquid or a mixture of solvent/non-solvent in a collecting bath (coagulation bath) used for fabrication of fibers by the dry-/wet-spinning technique or the wet-spinning technique. Coagulation of the external surface of the nascent fiber can start immediately after its extrusion from the spinneret (wet spinning) or after the as-spun fiber crosses an air

gap (i.e., distance between the spinneret and the coagulation bath) through which the external surface experiences coalescence and orientation of polymer aggregates (wet/dry spinning). In general, the nascent fiber is partially coagulated by the internal coagulant (bore liquid) and/or through the air gap by solvent evaporation, and finally the coagulation is completed in the coagulation bath by an external coagulant.

The type of the external coagulant affects considerably the structural morphology of the resulted fiber. Usually, water is the preferred external coagulant because of its low cost and environmental friendliness. The proper choice of the coagulant is very important because the rate of demixing (i.e., phase separation) and the resultant inner and outer surface structures of the hollow fiber strongly depend on the chemistry and the composition of the coagulant. The molecular sizes and solubility parameters of the used solvent and the internal and the external coagulant play important roles on hollow fiber morphology. Solvent of a large size may have difficulties to leach out during the coagulation step. The difference in solubility parameters between the spinning dope solution and the bore liquid (internal coagulant) or the external coagulant affects the coagulation rate and subsequently the porosity of the spun hollow fiber membrane.

The interactions between solvent and external coagulant and between solvent and polymer play important roles affecting the rate of polymer precipitation. The temperature of the external coagulant affects also the polymer precipitation rate. The maximum amount of solvent that can be added to the non-solvent in the coagulation bath can be roughly determined by the position of the binodal (liquid-liquid boundary separating the miscible region from the immiscible one) in the ternary phase diagram presenting the composition of the polymer, solvent, and non-solvent. When the binodal shifts toward the polymer/solvent axis, more solvent can be added in the external coagulant. It is also possible to change from porous to nonporous external fiber surface by adding solvent to the coagulation bath (Mulder 1992). For example, when a strong coagulant such as water for poly(vinylidene fluoride),

External Coagulant in Fiber Preparation, Fig. 1 Cross-sectional scanning electron microscopy (SEM) structure of PVDF hollow fiber membranes prepared with different coagulants: (a) water coagulant;

(b) internal coagulant water and external coagulant 50 % ethanol in water (Reprinted from (Khayet et al. 2002). Copyright 2002, with kind permission from Elsevier)

PVDF, polymer is used for hollow fiber fabrication, a dense and smooth surface with no obvious pores is formed. However, when a weaker coagulant is employed such as methanol, which may be mixed with water, the roughness of the formed hollow fiber surface may increase considerably due partially to the formation of pores. These are the reasons for using the coagulants: 80 wt.% N-methylpyrrolidone (NMP) aqueous solution by Wang et al. (2008) for preparation of PVDF hollow fiber membranes and 80 wt.% methanol aqueous solution by Bonyadi and Chung (2007) for fabrication of dual hydrophilic/hydrophobic hollow fiber membranes for direct contact membrane distillation (DCMD) process. Figure 1 shows the effects of the external coagulant on the cross-sectional structure of porous hydrophobic hollow fiber membranes (Khayet et al. 2002). Water and 50 % (by volume) ethanol in water were used as internal and external coagulants. In Fig. 1a prepared with water as internal and external coagulants, long finger-like voids are formed near the inner surface, while smaller cavities are formed near the outer surface. Between the inner and outer layers, sponge-like structure appears. In Fig. 1b the outer layer is eliminated when ethanol is added to the external coagulant. The addition of ethanol delays the external coagulation process and the finger-like structure changes to a sponge-like structure. The slow coagulation of the hollow

fiber membranes can be explained on the basis of the mutual diffusivity of solvent/non-solvent exchange and solubility parameters of the materials involved in hollow fiber spinning. The addition of ethanol in water reduces the diffusion of non-solvent into the nascent hollow fiber membrane and consequently decreases the rate of precipitation. Khayet et al. (2002) observed an increase of the external surface roughness of PVDF hollow fibers when ethanol was added to the external coagulant and attributed the result to the increase of the pore size at the outer surface as ethanol was added in the coagulation bath.

Extracellular Polymeric Substance (EPS)

Loreen O. Villacorte

FMC Technologies, Separation Innovation and Research Center, Arnhem, The Netherlands

Extracellular polymeric substances or EPSs are biosynthetic polymers from prokaryotic (bacteria, archaea) and eukaryotic (algae, fungi) microorganisms, which either form (loose or tight) slimes around the microbial cells or are excreted as discrete gels to the surrounding environment. Typically, EPSs are heterogeneous mixtures of polysaccharides, proteins, nucleic acids, lipids, and other polymeric compounds. The highly diverse chemical composition of EPS is a result of the different processes related to their production and their immediate environment: active microbial secretion, shedding of cell surface materials, cell lysis, and adsorption from the environment (Wingender et al. 1999).

EPSs are often associated with the formation of biofilms and microbial aggregates. In biofilm systems, they are mainly responsible for binding cells and other particulate materials together and to the solid-liquid interface (Characklis and Wilderer 1989). In surface water sources, suspended EPSs are responsible for the formation of large aggregates of organic and inorganic suspended materials including living and dead microorganisms in the water (e.g., marine snow or mucilage). These aggregates are held together by a type of EPS mainly comprising of surface-active, algae-derived anionic polysaccharides collectively known as transparent exopolymer particles (Alldredge 2002). The latter has been recently identified as one of the major initiators of aquatic biofilms as it can form conditioning films on the solid-liquid interface conducive for bacterial attachment (Bar-Zeev et al. 2012).

Over the years, the important role of EPS in the microbial activities in natural aquatic systems is widely recognized. Moreover, it has also been identified to cause serious problems in technical systems ranging from the shipping industry,

power industry, microelectronics, and food industries to water purification (Flemming et al. 2009). In water supply systems, such problems are due to either organic or biological fouling of reservoirs, pipelines, media filters, and separation membranes.

EPS accumulation in membrane filtration systems can cause increase of operating pressure and cleaning frequency due to blockage of membrane pores as well congestion along the feed channel (Flemming et al. 1997). In NF/RO systems, it can directly cause decline in permeate water quality (e.g., salt rejection) due to hindered back diffusion of rejected salts and can indirectly cause membrane damage due to long exposure of cleaning chemicals and very high feed channel pressure drop (Vrouwenvelder et al. 2011). It has been proposed that the removal of planktonic EPS from the feedwater by pretreatment with dissolved air flotation (DAF) and/or UF/MF membranes can effectively minimize biofouling in NF/RO systems. However, this is still subject to extensive debate and investigations.

During algal blooms, very sticky EPS materials (including TEPs) produced by phytoplankton and bacterioplankton can cause physically irreversible (or non-backwashable) fouling in dead-end MF/UF systems (Villacorte et al. 2010). In this case, chemically enhanced backwashing (CEB) can be effective in restoring membrane permeability. However, applying an optimal dose of coagulant (conventional or in-line) prior to membrane filtration has been found to effectively minimize the need for chemical cleaning (e.g., Schurer et al. 2012).

Introduction to Extracorporeal Blood Oxygenation

In physiology, respiration is defined as the transport of oxygen from the outside air to the cells

within tissues and the transport of carbon dioxide in the opposite direction. The heart and lungs work together to ensure the circulation and the exchange of the respiratory gases. During circulation, the heart pumps oxygen-depleted blood to the lungs and then receives oxygen-enriched blood from the lungs for distribution to the rest of the body. In the lungs, the gas exchange process takes place in grapelike clusters of air sacs known as the alveoli. There are about 300 million alveoli in the lungs with a combined surface area of approximately 70 m². This is the area through which the blood–gas exchange takes place (Weibel 2009). Fresh air entering the lung carries oxygen with a partial pressure of oxygen (P_{O2}) of 160 mmHg; the presence of moisture in the lung alveoli results in reduction of the P_{O2} to 104 mmHg. The same air that enters the lung carries carbon dioxide with a partial pressure of carbon dioxide (P_{CO2}) of 0.3 mmHg. The carbon dioxide delivered to the lung from the blood in the venous ends of the pulmonary capillaries raises the P_{CO2} in the alveoli to 40 mmHg (McArdle et al. 2005). At the arterial ends of the pulmonary capillaries, oxygen diffuses from the air in the alveoli into the blood, and carbon dioxide diffuses from the blood into the alveoli because of differences in partial pressures. The heart then receives the oxygenated blood from the lungs and distributes it to tissues in the rest of the body. In most tissues, the P_{O2} is less than 40 mmHg and the P_{CO2} is greater than 45 mmHg so, because of the differences in partial pressures, oxygen diffuses out of the arterial ends of tissue capillaries into the cells, and carbon dioxide diffuses out of the cells into the blood. The heart pumps the oxygen-depleted blood back to the venous ends of the pulmonary capillaries entering the alveoli with a P_{O2} of 40 mmHg and P_{CO2} of 45 mmHg (Fox 2007).

In June of 2011, the World Health Organization classified heart diseases as the worldwide number one cause of death (WHO 2011). The treatment of many cardiac-related diseases such as coronary artery bypass grafting, valve repair, and aortic aneurysm repairs involves complex open-heart procedures where surgeons need to operate on a motionless heart in an almost

standard therapy for the treatment of respiratory failure in neonatal patients (Grenvik et al. 1999; Roy et al. 2000).

In adult and pediatric patients, clinical ECMO is a treatment of last resort for individuals who would otherwise die despite maximal therapy (Bartlett et al. 2000). Since the 1990s, this treatment has grown continuously in the treatment of adult patients with respiratory dysfunction, for oxygenation and carbon dioxide removal, and as a lung-protective ventilatory strategy in order to “rest” the lungs and provide optimal conditions for the recovery of lung function (Ghosh et al. 2009). Despite the current limited application of ECMO in adults, a randomized controlled trial (RCT) is recruiting patients in the United Kingdom to evaluate the cost-effectiveness and clinical benefit of modern ECMO technique (Peek et al. 2006). This RCT will be one of the first RCTs performed in adults since the benchmark NIH trial during the 1970s (Zapol et al. 1979) and could reveal an increase in the rate of survival of patients with severe, but potentially reversible, respiratory failure without severe outcomes of disability, if technical and clinical advancements improve outcomes.

Clinical Practice, Risks, and History of Extracorporeal Blood Oxygenation

Blood is a complex tissue designed to sustain the body by continuous circulation within a vast network of blood vessels coated with endothelial cells. These unique cells simultaneously maintain the fluidity of blood and ensure integrity of the vascular system. Contact with the surgical wound and diversion of blood into the heart–lung machine trigger a massive defense reaction that stimulates all types of blood cells and five plasma protein systems to produce a myriad of vasoactive cytotoxic and cell-signaling substances into the circulation. Platelets, neutrophils, monocytes, and endothelial cells are the major cellular actors, and complement, contact, intrinsic coagulation, extrinsic coagulation, and fibrinolytic protein systems are the primary plasma participants. When activated, these cells and proteins initiate complex and overlapping reactions and interactions with a multitude of target molecules to create a whole

body inflammatory response (Kirklin et al. 1983; Edmunds and Colman 2006). Although the safety of CPB has been established with low mortality rates, it is still associated to risks such as blood clots and air bubbles that can cause embolism (occlusion of a blood vessel), hemolysis or damage to red blood cells, and immune system activation or systemic inflammatory response. Studies show that presently patients undergoing cardiac surgery with CPB can still experience systemic inflammatory response syndrome (SIRS) (Segal et al. 1998; Onorati et al. 2010). This results in severe and irreversible effects such as cerebral injury and cognitive impairment (Lund et al. 2005), endothelial injury (Verrier and Boyle 1996), organ dysfunction and impaired hemostasis (Hsu 1997) also known as the process of blood clotting, blood coagulation or thrombus formation, graft occlusion, perioperative strokes and pulmonary thromboembolism (Valley et al. 2010), and even postoperative morbidity and mortality (Hammon 2008; Valley et al. 2010).

In order to prevent in-circuit thrombosis, or clotting, patients undergoing CPB or ECMO require the administration of systemic anticoagulation agents. Unfractionated heparin, which suppresses the action of thrombin, the key enzyme in the thrombotic portion of the defense reaction, has been the elected anticoagulant for over half a century. Although the results are generally satisfactory, there are sometimes controversial effects due to (i) thrombin being, in certain patients, only partially suppressed by heparin (Janvier et al. 1996; Edmunds and Colman 2006) or (ii) major hemorrhaging even after the patients are subjected to correction of the coagulopathy with antifibrinolytic drugs (Chalwin et al. 2008). About 30–70 % of patients undergoing coronary artery bypass grafting under CPB require homologous blood transfusions (Scott et al. 1992). The major risks such as SIRS, activation of the blood coagulation cascade, blood cell trauma, thrombosis, clotting, hemorrhaging, etc., which patients submitted to CPB and EMCO encounter, are all due to the contact of the blood with foreign surfaces of materials with inadequate blood compatibility also

known as hemocompatibility. Among these surfaces contacting blood in the extracorporeal blood oxygenation system, the membranes for the gas exchange are of primordial importance due to their extensive surface area.

The start of the historical development of extracorporeal circulation is strongly related to C sar Julian Jean Le Gallois (1770–1814). In the monograph published in 1812, *Experiences sur le principe de la vie*, he suggested that a part of the body might be preserved by a mechanical heart replacement and some kind of external perfusion device (Le Gallois 1812). After the first idea of external perfusion devices by Le Gallois, the first attempts of oxygenating blood outside the body were made by the physiologist Alexander Schmidt, in 1876, when he perfused an isolated dog kidney with oxygenated blood (Kramme 2011). The original BO, invented by von Frey and Gruber (Kay 1992), in 1885 was the film BO; it used rotating cylinders to spread blood in a continuously renewed thin film while oxygen flowed over it. Though there was direct contact between the blood and gas phases, the gas exchange efficiency was low, leading to devices that had very large priming volumes. Using the same principle, John Gibbon, best known for inventing the heart–lung machine, developed his first film BO in 1937 (Gibbon 1937) and, after years of tests and improvements, performed the first successful open-heart surgery with extracorporeal blood oxygenation in 1953 (Gibbon 1954; Edmunds 2004). After this, several forms of supplying oxygen to the blood were attempted, with more or less success, enabling the development of many models of oxygenators of which only a few were clinically employed such as the bubble BOs. In these devices, the gas exchange efficiency was increased by dispersing bubbles of oxygen directly into the blood, which resulted in significantly reduced priming volumes compared to the film BOs (Cahn and Li 1974). On the other hand, bubbling gas through blood led to foam formation, and therefore defoaming agents such as silicone compounds had to be added to the blood (Kremesec 1981). In 1955, DeWall et al. performed the first successful CPB procedure using a bubble BO (DeWall et al. 1966). The

DeWall–Lillehei bubble oxygenator (Lillehei et al. 1955; DeWall et al. 1966) was a major breakthrough and well accepted by surgeons. It was a simple disposable device where oxygen bubbles were dispersed into an oxygenation chamber containing venous blood that was pumped from the patient’s body and then was defoamed in a defoaming compartment before returning to the patient. Although the benefits of bubble versus film BOs have been often debated, both have their own limitations. For film BOs, though the blood surface area was large, the gas transfer efficiency was often compromised by channeling of the blood flow (Niiya and Noble 1985; Ho and Sirkar 1992) and a very large priming volume was usually required to obtain sufficient gas exchange. On the other hand, bubble BOs caused significant damage to the blood due to the foam formation with devastating consequences such as denaturation of plasma proteins, gas emboli, fat emboli, fibrin emboli, and neurocognitive deficits (Lee et al. 1961, 1969; Hill et al. 1969). Despite the nonphysiological conditions of the blood–gas interface present in bubble oxygenators, these were used until 15 years ago in around 2–3 % of open-heart surgery worldwide (Wiese 2010).

Membrane Blood Oxygenators and Principle of Membrane Blood Oxygenation

Membrane blood oxygenators (MBOs) were first developed when the scientists introduced a nonporous symmetric membrane between the blood and gas phases to avoid direct contact between the two phases in an attempt to improve the hemocompatibility of BOs (Kolff and Balzer 1955; Clowes et al. 1956; Marx et al. 1962; Dorson et al. 1968; Guidoin et al. 1978). This represented a significant breakthrough in the development of blood oxygenation as the membrane provides a barrier in the blood–gas interface and that minimizes the risk of air embolism (Iwahashi et al. 2004). Microporous MBOs are, in fact, the state-of-the-art technology for extracorporeal blood oxygenation. Another advantage

Extracorporeal Blood Oxygenation Devices, Membranes for,

E

of MBOs is in the device design and fabrication which, because of the defined blood channels, allows for precisely controlled blood flow characteristics and, therefore, possibilities for optimal efficiency in gas exchange.

As in the natural lungs, transport of gas into blood is driven by the partial pressure difference of the respiratory gases between the blood and the gas separated by the membrane. According to the pressure differences, gas diffuses through the membrane from the side of high partial pressure to the side of low partial pressure. Figure 2 schematically shows the principle of membrane blood oxygenation. In order to be clinically functional for an average healthy adult weighing around 70 kg, at rest, the MBO must deliver, at standard temperature and pressure conditions, approximately 250 mL of oxygen per minute and remove the corresponding carbon dioxide production of about 200 mL per minute. The controlling factor in the design of these blood–gas exchange devices is the permeability of the membranes toward oxygen and carbon dioxide. The equivalent oxygen partial pressure in venous blood is about 40 mmHg and about 104 mmHg for arterial blood. Use of air as the supply gas and at ambient pressure gives a driving force for oxygenation of about 88 mmHg. In contrast, in venous blood, the CO₂ partial pressure is about 45 mmHg which, assuming that the exchanging air has negligible CO₂ content, constitutes the maximum driving force for CO₂ removal from the blood. The initial challenge in membrane technology was to produce reliable membranes with high permeabilities for oxygen, and much

emphasis was placed on oxygen transfer as the controlling factor in the design of the blood–gas exchanger system. However, in some cases, removal of CO₂ from the blood may be a limiting factor in the design (Bungay et al. 1986; Stamatialis et al. 2008).

Development of Membrane Blood Oxygenators

The very first discovery of oxygen transfer across an artificial membrane was made by Kolff and Berk in 1944 when they found that venous blood was being oxygenated while flowing through a cellophane dialyzer that was in contact with oxygen containing dialysate (Kolff et al. 1944). This discovery stimulated the development of the use of gas permeable membranes in order to separate the blood phase from the gas phase in the BOs.

The first plate-type membrane oxygenator was built by Clowes Jr. in 1956 (Clowes et al. 1956). Clowes' membrane oxygenator was based on the Skeggs–Leonards (Skeggs et al. 1949; Skeggs 2000) plate dialyzer with its dialysis membrane replaced with a supported ethylcellulose flat sheet membrane. In order to have the sufficient oxygenating capacity for perfusion in an adult, it had to have a multilayered system with a very large membrane surface area of approximately 25 m².

In 1956, Kolff developed the first coil-type membrane oxygenator (Kolff et al. 1956b) by substituting the cellophane membrane in his own developed artificial kidney, the Kolff rotating

drum (Kolff 1954; Kolff et al. 1956a; Kolff and Watschinger 1956), with a nonporous symmetric dense polyethylene (PE) membrane. The blood flowed in a spiral mode, whereas the oxygen flowed parallel to the axis of the cylinder. To use this membrane oxygenator for an adult patient, it was necessary to assemble eight coil units with an enormous membrane surface area for effective gas exchange (Kolff et al. 1956a).

The second generation of nonporous symmetric membranes appeared in the 1960s with the development of silicone rubber which displayed increased oxygen and carbon dioxide permeabilities. The carbon dioxide permeability of silicone is about five times greater than the oxygen permeability, and this partially compensates for the smaller available driving force for carbon dioxide transfer (Haworth 2003). Since the diffusion coefficient of oxygen and carbon dioxide in air is about four orders of magnitude higher than in blood, the gas-side mass transfer resistance was negligible. The major resistance to respiratory gas transfer was due to the membrane and the blood-side concentration boundary layer (Weissman and Mockros 1969). This brought about a major advance in establishing the technical feasibility of membrane oxygenators in the 1960s and 1970s as the required membrane area could be optimized to less than 6 m^2 . Kolobow took advantage of the development of silicone rubber and in 1963 developed an oxygenator utilizing the same configuration of Kolff's coil lung but with a different assembly. A silicone rubber envelope reinforced with nylon knit was wrapped around a central core, and pure humidified oxygen was passed through it under a negative pressure. The blood flowed across the flat tubing parallel to the axis of the cylinder. The average priming volume of these units was of 0.1 L/m^2 , and they could oxygenate venous blood at rate of approximately $1 \text{ L/m}^2/\text{min}$ (Kolobow and Bowman 1963). In 1965, Bramson et al. commercialized the first disposable nonporous symmetric silicone MBO with an integrated heat exchanger (Bramson et al. 1965). In 1971, Kolobow (Kolobow et al. 1971) improved his first disposable coil membrane oxygenator by using membranes fabricated from silicone rubber deposited on a fabric

with an irregular structure. This membrane was originally manufactured by Fuji Systems in Tokyo, and its unique structure permitted enhanced secondary flow effects that improved the gas exchange capability. The improved Kolobow oxygenator was successfully used in the clinical field, first as an oxygenator for CPB during cardiac surgery, and later in respiratory assist devices was the only oxygenator available for long-term application of ECMO for acute respiratory failure patients (Kolobow et al. 1971). In 1972, J. P. Hill reported the first successful treatment of adult respiratory distress with ECMO (Hill 1977), and after 3 years of this success, the first neonatal ECMO survival case was described by R. H. Bartlett (Bartlett et al. 1976). This was the beginning of successful ECMO application, and it has been shown to be most effective in the treatment of newborn and pediatric patients (Bartlett et al. 1982).

The real breakthrough in MBOs came in the 1980s with the development of hydrophobic microporous membranes. These membranes were made from polytetrafluoroethylene (PTFE) and the membrane pore diameters ranged from 0.02 to $0.1 \mu\text{m}$. The respiratory gases pass through the membrane pores rather than diffuse through the membrane material and, consequently, offer a much lower resistance to gas transfer than the nonporous membranes. Polypropylene (PP) microporous membranes were introduced soon after and displaced the PTFE membranes because they have lower cost and better mechanical properties, which offered better control of the blood channel geometry (Haworth 2003).

In 1981, Y. Nose (Nosé and Malchesky 2000) started to work on the first microporous hollow fiber membrane oxygenator – the Monsanto oxygenator. Although the gas exchange characteristics were reasonable, the device leaked a large amount of plasma through the membrane walls. The first commercially available hollow fiber oxygenators, the Capiox MBO, composed of PP microporous membranes was developed in 1981 by Terumo Corporation (Terumo Corporation, Tokyo, Japan) and Suma (Suma et al. 1981). In order to avoid plasma leakage, the inner surface of the microporous PP hollow fibers was coated with

a silicone layer with a thickness of approximately 0.2 μm . In these two MBOs, the blood was pumped inside the bundle of hollow fibers (luminal flow), while the gases circulated on the outer side. As the venous blood entered each fiber, it was surrounded by an oxygen-rich ventilating gas mixture which passed through the fiber walls into the bloodstream (Weissman and Mockros 1968; Dutton et al. 1971; Suma et al. 1981; Tanishita et al. 1994). It was soon found that, for routine short-term perfusion, these types of MBOs presented no real advantage over bubble models mainly due to thrombus formation within the fibers (Calafiore et al. 1987; Bergdahl and Bergdahl 1989). In the 1980s, microporous MBOs with intraluminal flow accounted for only 20 % of all blood oxygenators sold in the United States (Voorhees and Brian 1996). At that time, the gas transfer performance of MBOs was not yet comparable with that of bubble blood oxygenators, and, furthermore, the MBOs were complex to operate.

The disadvantages presented by the MBOs triggered a series of studies on mass transfer efficiencies, pressure drops, and shear stresses through blood flow paths in different module configurations. Designers of flat sheet MBO modules focused on incorporating passive mixing of the blood to reduce the blood-side resistance to gas transfer, and in 1984, an oxygenator was introduced in the market by Cobe Cardiovascular (Cobe Cardiovascular, Arvada, Colorado), with a high gas transfer efficiency and a membrane surface area of only 2.5 m^2 . This was achieved through the introduction of spacers over the flat sheet microporous membranes to induce mixing on the blood side (Elgas and Gordon 1984). Extensive studies of MBO modules with hollow fiber intraluminal blood flow (Alpha et al. 1986; Gassman et al. 1987) led to the design of hollow fiber modules with blood flowing on the outside of the hollow fibers (extraluminal flow), while oxygen was administered through the inside of the membranes. In 1985, the Johnson and Johnson Extracorporeal Maxima Oxygenator (Johnson and Johnson Cardiovascular, Anaheim, California) was presented as a highly efficient and compact MBO. It contained microporous cross-wound

hollow fibers where the blood flowed over and under the outside of the fibers (extraluminal flow) while oxygen crossed from within the hollow fibers into the blood (Iatridis et al. 1985). In the 1980s, the Kuraray Corporation (Osaka, Japan) began on the development of a new device – the MENOX oxygenator – that contained a silicone-coated microporous polyolefin membrane. The reason behind the silicone coating is to reduce the plasma leakage through the membrane pores and to correct any defects at the surface of the membrane. The developers claim that the membranes are non-plasma-leaking and that the MENOX oxygenator could be used in ex vivo experiments for up to 5 months (Nosé 2001). Another coating developed by Medtronic Inc. (Minnesota, USA) comprised of an alkoxysilane/alkylsilane copolymer, preferably aminoalkylsiloxane, was used to coat microporous hollow fiber membrane blood oxygenators, increasing the resistance of the fibers to passage of blood plasma through the micropores (Plunkett 2002).

Nevertheless, in both cases, the coating provides an additional layer or “second skin” and introduces an additional barrier to the gas transfer, altering therefore a severe limiting factor of the oxygen mass transfer to the blood.

The technological advances of MBOs developed during the 1980s permitted the increase of the gas transfer efficiency and reduction of membrane surface area and priming volume. As a consequence of these improvements and with the general migration from blood flowing in the luminal to the extraluminal space of hollow fibers, by 1992, MBOs accounted for more than 98 % of all blood oxygenators sold in the United States.

State of the Art of Commercial Membrane Blood Oxygenators

The technical and medical progress of MBOs has been intrinsically associated to the development of membranes that can assure physiological transport rates of oxygen and carbon dioxide and of module configurations that are compact with minimal membrane surface area per unit volume and with low resistance to oxygen transfer, particularly on the blood side.

A membrane, in a very general sense, is a semipermeable barrier that can be made of inorganic or organic materials. In MBOs, organic polymers are the membrane materials of selection due to their physicochemical and structural versatility. According to their structure, membranes can be divided in four main categories: nonporous symmetric membranes, microporous membranes, integral asymmetric membranes, and composite asymmetric membranes. All of them can be processed in the form of flat sheets or hollow fibers (Bungay et al. 1986; Mulder 1996; Baker 2004). Nonporous symmetric membranes consist of a dense film where the selective transport of gases is governed by a solution/diffusion mechanism. Microporous membranes have a rigid, highly voided structure with randomly distributed, interconnected pores of different shapes and sizes from 0.01 to 10 μm in diameter depending on the preparation process. Asymmetric membranes, first developed by Loeb and Sourirajan in 1963 (Loeb 1981), consist of two layers: a dense and nonporous symmetric active “skin” layer with thickness ranging from 0.1 to 50 μm and a relatively thick porous support layer with thickness between 50 and 500 μm . The overall performance of the membrane is governed by the top dense layer, while the porous sublayer provides mechanical strength to the membrane. When the material of the top layer and porous sublayer are the same, the membrane is called an integral asymmetric membrane and when composed of different materials known as asymmetric composite membranes.

The packaging and arrangement of the membranes play a fundamental role in the development of MBOs. Efficient packaging of large surface areas of membrane into small volume devices lead to MBOs of high gas transfer rates and low priming volumes. Furthermore, the blood flow path must be carefully designed. While disrupting the blood-side mass transfer boundary layer will lead to higher gas transfer efficiencies, it also leads to increased shear stresses on the blood cells. Damage to blood cells depends both on the applied shear stress and on the time for which the shear stress is applied (Zydney 1985). Thus, while mixing on the blood side is desirable, it is essential

to ensure that the blood cells and blood components are not damaged.

Early microporous MBOs contained up to 5.5 m^2 of membrane surface area (Von Segesser 1987), so, in order to overcome slow gas transfer rates due to the high blood-side mass transfer resistance, modern MBOs have utilized secondary flow effects to disrupt the blood-side concentration boundary layer and hence reduce the membrane surface area and priming volume. In the case of flat sheet MBOs, such as the Cobe CML 30 (Cobe Cardiovascular, Arvada, Colorado, USA) (Voorhees and Brian 1996), the membrane surface area has been reduced to between 2.5 and 3.0 m^2 , whereas for hollow fiber designs with extraluminal blood flow such as the Cobe Optima (Medtronic Maxima, Medtronic, Anaheim, California, USA) (Ulrich 1990), the membrane surface has been reduced to between 1.7 and 2.3 m^2 .

In developed countries, the rate of growth of the elderly population is exceeding the growth rate of the rest of the population, and this means that in the near future cardiac surgery will be performed on older and less healthy patients, some of which may even need to undergo more than one operation (Voorhees and Brian 1996). This changing patient population as well as clinical and economic factors will demand improved MBOs. Designing improved and novel MBOs is a complex procedure given the interdependence of the important design variables as described below:

- Maximizing the gas transfer per unit priming volume of the device is essential. In the past, the patients’ body temperature was lowered by cooling the blood during CPB, thus reducing the oxygen requirement. In current practice, there is a trend toward normothermic coronary perfusion which increases the oxygen requirement (Galletti 1993). In addition, the need to minimize the transfusion of donated blood due to possible transmission of pathogens will drive module design toward lower priming volumes (Voorhees and Brian 1996).
- Minimizing the membrane surface area of the device has clinical and economic benefits. During CPB surgery, hematological and immune

responses are observed as a result of contact between the blood and oxygenator surfaces. While these side effects are relatively minor in healthy patients, they are of concern for older and less healthy patients. An increased gas transfer efficiency would allow a reduction in membrane surface area and hence a reduction in the average contact time between the blood and foreign surfaces. Since the membrane is often the most expensive component in a MBO, minimizing the membrane surface area will reduce manufacturing costs.

- The blood flow path must be carefully designed. While disrupting the blood-side mass transfer boundary layer will lead to higher gas transfer efficiencies, it also leads to increased shear stresses on the blood cells. Damage to blood cells depends both on the applied shear stress and the time for which the shear stress is applied (Kolff et al. 1944). Thus, while mixing on the blood side is desirable, it is essential to ensure that the cells are not damaged.

In the last decade, rather than focusing on the research of novel blood oxygenation membranes, most researchers have been concerned with blood flow configurations for mass transfer enhancement in hollow fiber MBOs. Extraluminal blood flow may be concurrent, crosscurrent, or counter-current to the flow of gas within the fibers, and all these flow patterns have been studied. Some researchers demonstrated that a hollow fiber module, in which the hollow fibers are perpendicular to the blood flow, is the most efficient as it promotes the disruption of the momentum and concentration boundary layer on the blood side. The subsequent decrease of the resistance to gas mass transfer leads therefore to the increase of oxygen transfer rates (Mockros and Leonard 1985; Yang and Cussler 1986, 1986; Rajasubramanian et al. 1997; Wickramasinghe and Han 2005). However, this blood flow arrangement complicates the design of oxygenators because of the complex blood flow path and the non-applicability of conventional mass transfer correlations. As a consequence, many studies of momentum and mass transfer in MBOs have been

carried out (Vaslef et al. 1994; Gabelman and Hwang 1999; Wickramasinghe and Han 2002; Taskin et al. 2010). Nagase et al. (2005a, b) have thoroughly investigated the relationship between the oxygen transfer rate and hollow fiber arrangement and found better mass transfer performance in parallel flow hollow fibers. This was due to the fact that in the hollow fiber module with blood perpendicular flow, the hollow fibers in the front layer conceal those in the rear layer at the cross-over point, and this decreases the mass transfer rates. Furthermore, the membrane surface areas of these parallel modules were larger than the ones in the other modules. Other studies show that high gas transfer rates can be obtained when microporous hollow fiber membranes are arranged in an orderly way in cross-laid double layer mats at an optimal membrane angle (Catapano et al. 2001).

The MBOs used in ECMO for long-term lung support system applications in infants and adults account for a very small part of the MBOs used worldwide. The flat sheet coil-type modules are generally composed of a nonporous, dense flat sheet reinforced silicone rubber membrane envelope in a spiral coil around a polycarbonate spool. The blood flows between turns of the envelope in a thin film, and oxygen from the gas compartment diffuses through the membrane into the bloodstream. At the same time, carbon dioxide diffuses through the membrane into the gas compartment and is flushed from the oxygenator by the oxygen flow. More recent oxygenators aimed for long-term ECMO usage are based on hollow fiber silicone-based membranes with extraluminal blood flow (Kawahito et al. 2002a, b; Motomura et al. 2003).

Hollow fiber and flat sheet MBOs have almost equivalent hemocompatibility and gas exchange performance. However, the gross air handling is different due to differences in the packing density defined by the total available membrane surface area per unit volume. Gu et al. (2000) compared flat sheet and hollow fiber MBOs in terms of pressure drop, shear stress, and activation of leukocytes or white blood cells. They found that both configurations displayed similar gas transfer performance. However, the pressure drop along the blood flow path of the flat sheet MBOs was higher

than that for hollow fiber MBOs. Moreover, activation of leukocytes in flat sheet MBOs was greater. De Somer et al. (1996) compared flat sheet and hollow fiber MBOs in terms of hemolysis, shear stress, and white blood cell and platelet counts and found that although they have important differences in pressure drop and shear stress, no statistical differences were found in hemolysis generation or other tormented blood elements. Therefore, pressure drop as a single element may not be considered to influence hemocompatibility.

A tremendous amount of research, as evidenced by the numerous scientific articles and patents, has been devoted to the design of the MBOs available today. In 1999, the total BO market was worth about \$460 million and by 2001 had risen to over \$500 million (Hanft 2002). In 2008, an estimated 1.4 million MBOs were used worldwide for acute surgical CPB, corresponding to a consumption of approximately 3 million km² of oxygenation membranes (Wiese 2009).

Presently, most of the MBOs sold worldwide contain hydrophobic microporous membranes, and more than 95 % of them are composed of extraluminal flow microporous hollow fiber membranes with pore sizes below 0.1 μm , outer diameters between 300 and 500 μm , and surface areas of approximately 2 m². The hollow fiber membranes are assembled into carefully spaced cross-laid double layer woven mats which provide uniform extraluminal flow channels for the blood (Hanft 2002). The main polymers used in the production of the blood oxygenation membranes are polyolefins such as polypropylene (PP), polyethylene (PE), and poly-4-methylpentene (PMP) and, at a smaller scale, polyvinylidene fluoride (PVDF) and silicone rubber (Wiese 2009).

Current Problems

Extracorporeal membrane blood oxygenators (MBOs) used in the medical field to substitute the respiratory function of the lung have at their very core membranes that act as a blood–gas barrier and ensure oxygen delivery and carbon dioxide removal from the patient’s bloodstream.

In order to be technologically feasible, the MBOs, with minimal membrane surface area, have to comply with two main properties: (i) be efficient gas exchangers and provide physiological oxygen and carbon dioxide transfer rates of approximately 250 cm³ per minute and 200 cm³ per minute, respectively, at standard temperature and pressure conditions and (ii) be hemocompatible.

The majority of current MBOs are made of hollow fibers of microporous hydrophobic materials with pore sizes below 0.1 μm . The resistance of these membranes toward the respiratory gases is very low as the gas exchange between the blood side and the gas side is performed by diffusion and convection of oxygen and carbon dioxide via the open pores. MBOs with these types of membranes have high gas permeabilities and are routinely used to provide temporary cardiopulmonary bypass (CPB) during open-heart surgery and are also occasionally used for extracorporeal life support (ECLS) to substitute short-term cardiopulmonary function in patients with respiratory failure. One of the drawbacks of microporous hydrophobic membranes is plasma breakthrough which occurs when plasma protein layers are formed at the membrane surface and grow through the membrane pores increasing the surface energy of the pore, allowing plasma to leak through from the blood side to the gas side (Montoya et al. 1992).

Another main concern that has troubled the membrane industry for the past 30 years and to date remains a serious issue is the blood compatibility or hemocompatibility of the oxygenation membranes. The definition of biocompatibility has been updated for over 20 years and can be considered as being the body’s acceptance of the material, i.e., the ability of an implant surface to interact with the cells and fluids of the biological system and to cause exactly the reactions which the analogous body tissue would bring about (Ratner 1993; Williams 2008). Presently, the biomaterials community has been unable to more accurately assign the term “blood compatible” to a given biomaterial in spite of 50 years of intensive research on the subject. There is no clear consensus as to which materials are “blood compatible” as blood material interactions are complex and involve multiple factors including

surface chemical composition, charge, flexibility, wettability, and conditions of blood flow (Cazenave 1987). Furthermore, unlike biocompatibility assays, there are no standardized methods to assess blood compatibility (Ratner 2007). Labarre's (2010) tentative definition of a blood compatible surface is "a surface able to keep under control coagulation and inflammation processes at its interface with normal blood, in given hemodynamic conditions." According to Ratner, we still do not have truly blood compatible surfaces after 60 years of intense research of blood compatibility and after numerous approaches have been tried (Ratner 2007). The hemocompatibility of biomaterials is known to be dependent on various surface properties such as surface morphology, surface chemical composition, surface charge, surface wettability, and surface topography. The overall blood-contacting surfaces must avoid damage to the blood cells and components but also to avoid stagnation and localized clotting.

To improve blood compatibility of transport surfaces such as the ones in MBOs, researchers have focused mainly on surface modification techniques and producing hemocompatible surface coatings. Minimization of blood/material interactions can be achieved through chemical modification; however, these methods are still far from perfect. Surface chemical modification, besides requiring rather complex experimental procedures and involving high costs, still does not offer surfaces with long-term stability and leads to potential complications downstream (Klee and Höcker 2000). Most manufacturers have focused on the development of anticoagulant-based coatings for the entire bypass circuit including the oxygenation membranes. This approach led to the commercialization of microporous-coated membranes and bypass-coated circuits. Various manufacturers claim that the added layer of material provides a blood-surface interaction with improved hemocompatibility compared to that seen for the bulk fiber materials. For example, heparin is known to have good blood compatibility properties and has been used as a coating on several commercialized products. Unfortunately,

heparin-based coatings are inherently expensive and complex due to the use of sodium heparin, a complex, costly, and fragile biologically derived substance. The Carmeda Bioactive Surface (Medtronic, Inc.) uses a polymer primer coat followed by covalent attachment of heparin to primary amino groups present in the primer coat (Stenach et al. 1992; Spiess et al. 1998). The Duraflo Bonded Heparin Surface (Baxter, Inc.) uses a heparin-polymer blend-based coating that is intended to achieve similar results (Toomasian et al. 1988; Mottaghy et al. 1989). Other heparin-based coatings intended to improve blood compatibility are available from other medical device manufacturers such as Terumo (Fukasawa 1983), 3M Sarns (Zacour 1988; Fried and Bell-Thomson 1992), etc.

Despite these developments, in order to prevent in-circuit thrombosis, or clotting, when subjected to extracorporeal blood oxygenation using any of the MBOs available on the market, patients still require the administration of anticoagulant drugs that often lead to major hemorrhaging and blood transfusions.

Another approach to improve the hemocompatibility of membranes destined for MBOs focuses on the development of novel blood oxygenation membranes made from materials different to the polyolefins mentioned before. Polyurethanes (PUs) first found a niche in biomedical applications mainly because of their unique mechanical properties, particularly fatigue resistance, tensile strength, and abrasion (Szycher and Poirier 1983; Szycher et al. 1983; Graig 1983; Gogolewski 1989; Hepburn 1992; Furukawa 1997), but also because of their good bio- and hemocompatibility properties (Boretos 1980; Wang and Cooper 1983; Yoon and Ratner 1988; Gogolewski 1989). PU membranes are a good candidate for blood oxygenation devices as the type, length, ratio, and crystallinity of the different monomers as well as the method of membrane preparation determine the bulk properties responsible for the final mass transfer properties (Yilgör and Yilgör 1999; Hoshi et al. 2000; Jonquière et al. 2002) and the surface properties that affect bio- and hemocompatibility (Yoon and Ratner 1988; Gogolewski 1989).

Blood Compatibility and Membrane/Blood Interfaces

In 2007, an estimated 250 million polymeric devices contacting the bloodstream were used in humans. All of these blood-contacting devices exhibited thrombosis problems, and all cardiovascular device procedures, both short term and long term, required significant anticoagulation, at high cost and with considerable risk to the patient (Geckeler et al. 1997). The number of blood-contacting medical devices used worldwide is increasing every day, but their hemocompatibility properties still remain far from ideal.

To this date, there is no consensus definition of blood compatibility. In 2007, Buddy Ratner labeled as a “catastrophe” the fact that the scientific community has still not been able to accurately assign the term “blood compatible” to a biomaterial in spite of 50 years of intensive research on the subject (Geckeler et al. 1997; Ratner 2007). While the definition of biocompatibility is generally accepted as the ability of a material to perform with an appropriate host response in a specific application (Williams 1987), blood compatibility or hemocompatibility has received different definitions by various authors. From a clinical point of view, a biomaterial can be considered as blood compatible when its interaction with blood does not provoke either any damage of blood cells or any change in the structure of plasma proteins. Only in this case can it be concluded that this material fulfills the main requests of biocompatibility (Gurland 1987). A tentative definition, by Labarre (2010), of a blood compatible surface is “a surface able to keep under control coagulation and inflammation processes at its interface with normal blood, in given hemodynamic conditions.”

The contact between the blood and the surface of a biomaterial often leads to different degrees of clot formation, as a consequence of the nonspecific protein adsorption and adhesion and activation of blood cells (Horbett 1986; Courtney et al. 1994). Within the first few seconds after blood contacts, material surface plasma proteins are deposited. The extent of protein adsorption depends on the properties of the foreign surface, namely, the wettability, charge, roughness,

chemical composition, etc. This protein layer controls further reactions of the other blood components and cell system. Additionally, the adsorbed proteins are subject to conformational changes as well as exchange processes with other proteins (Ziats et al. 1988). The competitive adsorption behavior of proteins at the material surface determines the pathway and the extent of intrinsic coagulation and adhesion of platelets. Platelets play a fundamental role in hemostasis. Following the protein adhesion to the surface of the biomaterial, coagulation is initiated by platelets adhering to specific binding sites exposed by the plasma proteins. The activated platelets swell, grow spiky extensions known as pseudopodia, and release the contents of their secretory granules, which contain a variety of substances which include ADP, serotonin, and thromboxane A₂, which stimulate further platelet adhesion and activation and enhance the coagulation process. A large variety of clotting factors take part in a series of chemical reactions that eventually create a mesh of fibrin fibers. Each of the clotting proteins has a very specific function, and the three main ones are prothrombin, thrombin, and fibrinogen. Thrombin promotes the conversion of fibrinogen into long insoluble fibers or threads of another protein – fibrin. Fibrin threads wind around the platelets forming an interlocking network of fibers and a framework for the clot. This net of fibers traps and helps hold platelets, blood cells, and other molecules tight to the material surface, forming a blood clot also referred to as a thrombus.

It has long been established, in the field of biomaterials, that bio- and hemocompatibility is mainly governed by the surface properties of the material that contacts the blood (Cooper 1982; Lelah and Cooper 1986; Schamberger and Gardella 1994). Predictions about the interactions between the biomaterial surface and the adsorbed proteins can only be formulated by having an exact knowledge of the structure of the biomaterial's surface and the conformation of the adsorbed proteins. These interactions are determined both by the hydrophobic/hydrophilic, charged/uncharged, and polar/nonpolar parts of the proteins and the properties of the polymer surface such as chemical composition,

morphology, charge, wettability, and topography (Dawids and Bantjes 1986; Williams and Williams 1989; Stamm 2008).

Hemocompatibility properties of surface materials can be evaluated following the ISO10993-4 (Biological evaluation of medical devices, Part 4: Selection of tests for interactions with blood. Geneva, Switzerland: International Organization for Standardization; 2002) guidelines in terms of protein adsorption, hemolysis, platelet adhesion and platelet activation, whole blood clotting time, and clinical coagulation times.

Hemocompatibility properties of surface materials can be evaluated in vitro according to the ISO 10993-4:2002 standard (ISO standard) guidelines in terms of hemolysis, thrombosis, platelet adhesion and activation, protein adsorption, and clinical coagulation times. The three categories of effects on blood most commonly evaluated are hemolysis, thrombosis, platelet adhesion, and activation (Imai and Nose 1972; Goodman et al. 1989; Allmér et al. 1990; Haycox and Ratner 1993; Tze-Man et al. 1993; Bahulekar et al. 1999; ASTM International 2000).

Damage to the membrane of red cells, as a result of blood exposure to foreign materials, can be evaluated by the hemolysis test. Hemolysis can be assessed by quantification of released hemoglobin (Hb) after contact between blood and sample, according to the ASTM F 756-00 standard. The Hb concentration can be determined by colorimetry at 540 nm, with a UV/VIS spectrophotometer. In the cyanmethemoglobin method (Moore et al. 1981; Van Assendelft et al. 1996; Zwart et al. 1996), blood samples with a plasma Hb concentration below 2 mg/mL are diluted in PBS in order to obtain blood with a total Hb concentration of 10 ± 1 mg/mL. The contact between diluted blood and membranes with an area of at least 7 cm² is maintained for at least 4 h of static incubation at 37 °C, and after which the blood is centrifuged, the supernatants are analyzed for their Hb content. Two controls are commonly used: distilled water (positive control) and PBS solution (negative control). The hemolysis degree is expressed through the hemolytic index (HI), calculated as follows:

$$HI = \frac{[Hb]_{\text{released}} - [Hb]_{\text{negative control}}}{[Hb]_{\text{positive control}} - [Hb]_{\text{negative control}}} \times 100 \quad (1)$$

where $[Hb]_{\text{released}}$ is the concentration of Hb in the supernatant solution and $[Hb]_{\text{negative control}}$ and $[Hb]_{\text{positive control}}$ are the concentrations of Hb in the negative and positive controls, respectively. According to ASTM F-756, materials can be labeled nonhemolytic when the HI is between 0 and 2, slightly hemolytic when HI is between 2 and 5, and hemolytic when $HI > 5$.

Thrombosis can be evaluated through an assay based on the determination of the thrombus mass formed on the surface of the membranes after contact with static, recalcified blood, based on a modification of the gravimetric assay proposed by Imai and Nosé (1972) and Allmér et al. (1990). Samples of each membrane are cut into pieces with a surface area of 4 cm², and 250 μL of blood are carefully placed on top. The clotting process is then started by addition of 25 μL of 0.10 M CaCl₂ to the blood drop on the sample. The clotting process is stopped at different time periods by addition of distilled water. The thrombus formed at the surface of the membrane is fixed with formaldehyde and then washed with water. The thrombus mass is determined after drying the thrombus at 37 °C until a constant weight was reached. The results are expressed as a percentage of the thrombus mass formed on glass (positive control). A pre-weighted filter paper disk that followed the above procedure in parallel, but in the absence of a membrane sample and of blood, was used as a blank. From the thrombus mass formed on each sample, a thrombosis degree is calculated as a percentage of the thrombus mass formed on the positive control after subtracting the blank from each thrombus mass. A thrombosis degree of 100 % is assigned to the positive control;

$$\text{Thrombosis } \% = \frac{m_{\text{membrane}} - m_{\text{negative control}}}{m_{\text{positive control}} - m_{\text{negative control}}} \times 100$$

The interaction between platelets and the surface of the membranes can be evaluated by a technique often used by researchers based on the analysis of

Extracorporeal Blood Oxygenation Devices, Membranes for, Fig. 3 Diagram of the platelet spreading process divided into five shape categories for analysis and correlation between platelet categories and planimetrically determined platelet spread area. From *left to right*, the stages of spreading are defined as follows: stage I – round or discoid: no pseudopodia present; stage

II – dendritic or early pseudopodial: one or more pseudopodia with no evident flattening; stage III – spread dendritic or intermediate pseudopodial: one or more pseudopodia flattened, hyaloplasm not spread between pseudopodia; stage IV – spreading: hyaloplasm spread between pseudopodia; and stage V – fully spread: hyaloplasm extensively spread, no distinct pseudopodia

scanning electron microscopy (SEM) images (Goodman et al. 1989; Haycox and Ratner 1993; Tze-Man et al. 1993; Bahulekar et al. 1999). Platelet-rich plasma (PRP) is prepared by centrifugation of the pooled blood and is incubated with the membrane samples for 30 min at 37 °C. After incubation, the samples are fixed with glutaraldehyde post fixed with osmium tetroxide (OsO₄). After fixation the samples are dehydrated through a graded ethanol series to 100 % and dried by critical point drying. The dry samples are then observed by SEM. Quantitative and morphology analysis of platelets adhered to the surface of the membranes is carried out by imaging software.

In order to ensure the presence and activity of the platelets, glass is generally used as positive control for *in vitro* platelet response to foreign materials as it promotes enhanced adhesion and activation of platelets (Park et al. 1991; Amiji 1998).

The indicators of platelet adhesion used are platelet deposition (PD) and platelet coverage (PC), which are the number of adhered platelets/10,000 μm² of membrane surface area and the

percentage of the membrane surface area covered by platelets, respectively. The platelets are either passively attached and remain discoid and singular or may be activated subsequently. In the latter case, they progressively release their granule contents, thereby attracting further platelets, showing a typical shape change with flattening, formation of pseudopodia, and increasing area of contact. Scanning electron microscopic images of adhered platelets with magnifications of ×1,000 or ×2,000 magnification have been used by several authors for the quantitative analysis of platelet–material interaction. The extent of platelet spreading is examined by categorizing platelet shapes into five morphological forms describing increasing activation stages (I–V). These are discoid or round (stage I), dendritic or early pseudopodial (stage II), spread dendritic or intermediate pseudopodial (stage III), spreading or late pseudopodial (stage IV), and fully spread (stage V). The spreading stages and respective platelet areas are shown in Fig. 3 and defined in the legend (Allen et al. 1979; Goodman et al. 1984, 1989).

Extraction Index

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The extraction index is a measure of membrane operation performance of extracting a desired species from the feed/retentate side in order to have it as permeate. It can be defined/evaluated for any involved species. It gives an indication about the real advantages offered by using a membrane unit instead of conventional ones. The higher the variable value, the higher the performance of the membrane unit. It is defined as the ratio (Eq. 1) of the permeate flow rate of the species permeated through the membrane to that totally fed to the membrane unit. Equation 1 shows different ways for evaluating the extraction index:

$$\begin{aligned}
 \text{Extraction Index}_i &= \frac{\text{Permeate flow rate}_i}{\text{Feed flow rate}_i} \\
 &= \frac{\text{Permeate flow rate}}{\text{Feed flow rate}} \frac{\text{Permeate molar fraction}_i}{\text{Feed molar fraction}_i} \\
 &= \frac{\text{Permeate flow rate}}{\text{Feed flow rate}} \frac{\text{Permeate Partial Pressure}_i}{\text{Feed Partial Pressure}_i} \\
 &= \frac{\text{Permeate flow rate}}{\text{Feed flow rate}} \frac{\text{Permeate concentration}_i}{\text{Feed concentration}_i} \\
 &= \frac{\text{Permeate flow rate}}{\text{Feed flow rate}} \frac{\text{Permeate mass fraction}_i}{\text{Feed mass fraction}_i}
 \end{aligned} \tag{1}$$

The extraction index assumes a specific and more interesting form when a chemical reaction takes place inside the membrane unit such as in the membrane reactors since a desired chemical can

be fed in it but also produced by reaction. In this case, Eq. 1 has to take into account also the production term:

$$\text{Extraction Index}_i = \frac{\text{Permeate flow rate}_i}{\text{Feed flow rate}_i + \text{Production by Reaction for } i - \text{th}} \quad (2)$$

If the water-gas shift reaction is used as an example, the extraction index can be defined as the ratio of the H_2 permeated through the membrane to that

totally available in the feed stream both as H_2 molecules and also obtainable from other chemicals (e.g., CO) by reaction, to the membrane unit (Eq. 3):

$$\begin{aligned} \text{H}_2 \text{ Extraction Index} &= \frac{\text{Flow rate}_{\text{H}_2}^{\text{Permeate}}}{\text{Flow rate}_{\text{H}_2}^{\text{Available in the feed}}} \\ \text{in the MR} &= \frac{\text{Flow rate}_{\text{H}_2}^{\text{Permeate}}}{\text{Flow rate}_{\text{H}_2}^{\text{Feed}} + a \cdot \text{Flow rate}_{\text{CO}}^{\text{Feed}}} \end{aligned} \quad (3)$$

$$a = \begin{cases} \text{H}_2\text{O/CO feed molar ratio} & \text{per } \text{H}_2\text{O/CO feed molar ratio} < 1 \\ 1 & \text{per } \text{H}_2\text{O/CO feed molar ratio} \geq 1 \end{cases}$$

The extraction index (Barbieri et al. 2008) takes into account the hydrogen fed as H_2 molecules and that is contained in the feed stream in other chemicals (e.g., H_2O). The term (a flow rate CO feed) of the Eq. 3 considers the maximum H_2 extractable from the chemicals (other than hydrogen) present in the system. The coefficient (a) takes into account the defecting reactant (CO or H_2O) by means of the feed molar ratio $\text{H}_2\text{O/CO}$. It (a) is equal to the feed molar ratio if the latter is lower than 1 (CO in defect with respect to H_2O). It (a) will be equal to 1 when the CO exceeds the H_2O . As defined, the extraction index is determined by the membrane properties, feed molar ratio, and CO conversion achieved in the membrane reactor, at set operating conditions.

Extremophiles

Chiara Schiraldi and Mario De Rosa
Department of Experimental Medicine, Section of Biotechnology, Medical Histology and Molecular Biology, Second University of Naples, Napoli, Italy

The discovery of life in demanding environments continues to challenge conventional concepts of the growth-limiting conditions of many cellular organisms. Extremophiles may have diverse features; they may live at temperatures higher than 60 °C (thermophiles) or prefer colder sites, being able to grow between 5 °C and 20 °C; they may need pH <4 or >9 (acidophiles or alkaliphiles, respectively); or they can survive to high-salinity environments such as salty lakes (halophiles). They have been isolated in challenging biotopes from terrestrial solfataric fields to marine volcanic areas (Rothschild and Mancinelli 2001). The

Extremophiles, Fig. 1 Electron micrograph of *Sulfolobus solfataricus* MT4

phylogenetic assessment of the isolated species widens between Archaea, Bacteria, and Eukarya. There has been a steady increase in the isolation of these microorganisms documenting the enormous scientific effort in the last 30 years. Although major advances have been made in the last decade, our knowledge of the physiology, metabolism, enzymology, and genetics of this fascinating group of organisms is still limited. However there is little doubt that extremophiles will supply novel catalysts and will be a source of biomolecules with unique and biotechnologically relevant properties. It has been argued that membranes of extremophiles contain surfactants bearing unique stability that can be used in pharmaceutical and cosmeceutical formulations. Amylases, pullulanases, and glycosidases from hyperthermophiles were studied and proved efficient in starch biotransformation obtaining process throughput enhancement (Burg 2003). Trehalose-forming enzymes were found in *Sulfolobus shibatae* and *S. solfataricus* isolated in diverse solfatar fields worldwide (Fig. 1). Also lipases and esterases from thermophilic microorganisms and Archaea proved unique features (Schiraldi et al. 2002). Compatible solutes, of key importance for halophile survival, were isolated from *Halomonas* and *Marinococcus* species and thoroughly characterized proving their outstanding DNA/enzyme stabilization capacity; their commercialization was pursued by a

specifically founded company (bitop). Alkaliphilic enzymes were found as natural detergents, thus suggesting specific industrial interest. Psychrophilic enzymes may also be of applicative interest when biotransformations need to be carried out at low temperature. Other innovative products from extremophiles are cyclodextrins and polyunsaturated fatty acids, for which industrial applications are foreseen. Most of these kind of microorganisms isolated to date show specific needs to increase cell density. Recent alternatives to technological applications most commonly employed when the production of extremocompounds is approached at a bioreactor scale describe batch, fed batch, and continuous or in situ product removal fermentations in specifically developed bioprocesses. However, when large-scale production is needed for commercialization of these novel compounds, there is the need to bring together genetic and bioreaction engineering with separation techniques. The former prompted the development of specific plasmids and vectors to obtain a sound expression of extremophilic gene sequence and thus enzymes into mesophilic hosts; these recombinant strains are easier to cultivate, and the whole strategy is in fact recommended to solve the typical problems faced in extremophile-based bioprocesses and will serve to open up new opportunities for the development of unexplored fields such as renewable energies.

Extremozymes

Chiara Schiraldi and Mario De Rosa

Department of Experimental Medicine, Section of Biotechnology, Medical Histology and Molecular Biology, Second University of Naples, Napoli, Italy

The biocatalysts produced by extremophilic microorganisms, so-called extremozymes, are proteins with outstanding stability to temperature, pH, and organic solvents, thus becoming excellent candidates to improve industrial biotransformations (Schiraldi and De Rosa 2002). Polymer-degrading enzymes from hyperthermophiles, psychrophiles, and acidophiles may play an important role in food, detergent, and pulp and paper industry (e.g., amylases, pullulanases, xylanases, proteases). Extremozymes also include cellulases, proteases, pectinases, keratinases, lipases, esterases, catalases, peroxidases, and phytases. Owing to the unusual properties of these classes of enzymes, they are expected to fill the gap between biological and chemical industrial processes (Taylor et al. 2011). Despite this, actually few are the current processes based on these biocatalysts, the most known of which is the polymerase chain reaction (PCR) technology that in fact is based on DNA-modifying enzymes. Taq polymerase isolated from *Thermus aquaticus*. The use of this enzyme allowed the automation of PCR with a great advantage for research laboratories and industries. Beside this, few biocatalysts, used in diagnostics and starch liquefaction, are commercially produced by several biotechnology companies. Recently enzymes of interest in bioremediation have also been isolated from extremophiles: a thermoalkaliphilic catalase, which initiates the breakdown of hydrogen peroxide into oxygen and water, was isolated from *Thermus brockianus*, found in Yellowstone National Park, and operates over between 30 °C and 94 °C (pH range 6–10). Its outstanding

stability and wide operational range suggest application in hydrogen peroxide removal in pulp and paper bleaching, textile bleaching, food pasteurization, and surface decontamination of food packaging (Thompson et al. 2003). Enzymes isolated from psychrophiles, such as lipases, proteases, and cellulases, have been used as additives for the preparation of detergents working at low temperatures or in frozen food preparations. Furthermore, thermophilic enzymes have been used for the construction of optical nanosensors, stable and nonconsuming analytes. These innovative devices are based on the ability of thermophilic enzymes to bind the substrate at room temperature, without transforming it (de Champdoré et al. 2007). The binding of substrate to thermophilic enzyme is monitored as fluorescence variations of the enzyme. Many of these isolated enzymes have been cloned and expressed in mesophilic hosts to overcome the issues of extremophilic microorganisms cultivations, such as the unconventional fermentation parameters, special construction materials need, the low growth rates that are typical of most of these species, and the low biomass yield (despite the good enhancement proved in membrane bioreactors) (Schiraldi et al. 2001). The recombinant enzymes (Cimini et al. 2008), easily produced at high yield, may be commercialized, and furthermore, modern techniques like mutagenesis and gene shuffling will lead to in vitro tailored enzymes that are highly specific for countless industrial applications.

F

Facilitated Pervaporation

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

A facilitated pervaporation system usually refers to the combination of a pervaporation as a separation unit combined with a chemical reactor for esterification reactions or other equilibrium reactions. The “facilitation” then refers in fact to the reaction, and not the separation. The pervaporation unit removes the side product of the reaction (in case of esterification, this is water) so that the reaction equilibrium shifts to a higher product yield (Van der Bruggen 2010). Other reactions than esterifications can also be facilitated, on condition that they concern an equilibrium reaction and that the side product can be easily removed by a pervaporation membrane (as is the case for water in an organic reaction mixture). For bioconversions, the reaction product(s) are to be removed instead of the by-products, in order to enhance the activity of the microbial population. This is the case, for example, in the production of bioethanol and in ABE (acetone, butanol, ethanol) fermentations, where ethanol (or butanol) is removed by a hydrophobic pervaporation membrane. See also pervaporation membrane reactor and

pervaporation assisted reactor for further explanation.

However, facilitated pervaporation may rather be related to a hybrid membrane extraction system, as described by Bessarabov et al. (1999) for the separation of liquid olefin/paraffin mixtures in the range up to C6. Nonporous polymeric membranes are used in a membrane contactor and a high-boiling-point selective liquid extractant flowing along polymeric membranes between the extractor and the membrane stripper. The olefin components permeated through the polymeric films at elevated temperatures in a membrane stripper, making it possible to obtain pervaporation transport. This is schematically shown in Fig. 1 (Bessarabov et al. 1999).

Another approach to obtain a pervaporation effect is by the use of fixed recognition sites in membrane contactors (Touil et al. 2006), so that the selectivity needed for pervaporation is obtained in a pertraction process (in which a porous membrane without any selectivity is used). The combination of selectivity characteristic for pervaporation and the pertraction effect results in an enhancement, which can be denoted as facilitated pervaporation. Cyclodextrins, for example, can be used to form inclusion complexes of different stability with organic molecules in the separation of p-xylene, m-xylene, and o-xylene (Touil et al. 2006). Kusumosahyo et al. (2004) made a similar study on polyacrylic acid (PAA) membranes and concluded that the native PAA

Facilitated Pervaporation, Fig. 1 Facilitated pervaporation using a hybrid membrane extraction system (for olefin separation). *A* is an extraction module, *B* is a membrane pervaporation cell (Reprinted with permission of Elsevier from Bessarabov et al. 1999)

membrane was almost impermeable for the xylene isomers, and the incorporation of cyclodextrins in the PAA membranes resulted in membranes having a molecular recognition function, which selectively facilitated the transport of the xylene isomers.

A further use of the term facilitated pervaporation refers to the membrane material itself. Liu et al. (2011) incorporated Ag(+) loaded titania (TiO₂) microspheres into a poly(dimethyl siloxane) (PDMS) matrix for pervaporative desulfurization of model gasoline and demonstrated facilitated transport through these membranes, as could be seen from increased fluxes and separation factors. A similar enhancement effect was

obtained by the incorporation of carbon nanotubes (CNTs) in the pores of a polyvinylidene fluoride (PVDF) membrane (Sae-Khow and Mitra 2009), and for polyvinyl alcohol (PVA) membranes (Bryant et al. 1997), and many other publications can be found on similar effects in mixed matrix membranes, nanoparticles-enhanced membranes, and hybrid organic–inorganic membranes. Chemical modifications have also been studied for enhancement of pervaporation. Wu et al. (2002) studied cross-linked polydimethylsiloxane (PDMS) membranes modified by the sequential introduction of two different side-arm functional groups, $-(CH_2)_3OC_2H_5$ and $-(CH_2)_3NMe_2$, for the pervaporative recovery of p-cresol from aqueous streams, which was successful.

Assisted transport

Transport mechanism used to improve flux, permeability, and selectivity in separations by liquid membranes. Mass transport selectivity and transfer velocity in a liquid membrane are mainly determined by the solubility and the diffusion coefficient in the membrane phase of the component to be separated. The driving force of the transport process is the gradient of chemical potential, normally due to a concentration gradient between the feed and the product phases. Then, a component which is soluble in the membrane phase and whose concentration is different

at both sides of that membrane phase will be transported through it (Fig. 1a). The component does not react chemically in the liquid membrane, and then it remains in the same chemical form in the feed, in the membrane, and in the product phases. Transport will end when an equality of concentration of the component prevails on both sides of the membrane phase. In order to improve the effectiveness of the separation process, facilitated transport mechanisms have been described (Vitt et al. 2010), which maximize both the extraction velocity (flux through the membrane phase) and the reception capacity of the diffusing specie in the product phase. Moreover, facilitated transport mechanisms combine the process of extraction and stripping in a single unit operation, and they offer the possibility of transporting a component against its own concentration gradient (Ho and Li 1992; Kislik 2010). Two types of facilitated transport are usually considered: type 1 and type 2. In type 1 facilitation, a stripping agent is added to the product phase, which quantitatively reacts with the diffusing specie to yield a membrane-insoluble product (Fig. 1b). Thus, concentration of that specie is reduced to zero in the

Facilitated Transport, Fig. 1 Schematic representation of the different transport mechanisms in liquid membranes

product phase, resulting in a high concentration gradient across the membrane phase. In type 2 facilitation (carrier-mediated transport), a reagent is incorporated in the membrane phase to carry the diffusing specie across the membrane to the product phase. The carrier forms, reversibly with the specie to be separated, a compound which is soluble in the membrane. This compound is formed in the interface feed phase/membrane phase, it is transported through the membrane phase due to its concentration gradient, and it is broken in the membrane phase/product phase interface. The specie to be separated is then liberated in the product phase, and the carrier diffuses in the contrary way through the membrane phase, as a consequence of its concentration gradient, to the opposite interface, to initiate a new separation cycle (Fig. 1c). As the process ends when the concentration of the specie to be separated equalizes on both sides of the membrane phase, carrier-mediated transport can be improved by incorporating a chemical reaction on the receiving side, as illustrated in Fig. 1d. The concentration of the specie to be separated is reduced to practically zero on the product side through an auxiliary reaction in the product phase, to form an insoluble compound in the membrane. The transportation of two components is possible, both from the feed phase (Fig. 1e) or one from the feed phase (the component to be separated) and the other from the product phase (Fig. 1f). Both cases are known as coupled transport, the first being denominated cotransport and the second counter-transport.

Fat Hydrolysis, Membrane Operations of

Angela C. Macedo¹ and F. Xavier Malcata²

¹LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

²DEQ – Department of Chemical Engineering and LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

Lipids that are solid at room temperature are termed fats. In nature, most fats are triglycerides – consisting of a glycerol backbone, to which three individual fatty acid moieties are attached. The variety of fats in nature and their diversity in terms of physicochemical properties come from the number of combinations of the hundreds of existing fatty acid residues – which, due to their underlying metabolic synthesis pathway, are characterized by an even number of carbon atoms.

In view of their insolubility and the relevance to water-based life, fats often appear stabilized via emulsification in aqueous media; this is notable in the case of milk fat, with globules surrounded by a membrane containing proteins and phospholipids. Said native globules range in size from less than 1 μm to over 10 μm . The uneven size distribution provides larger globules with a tendency to float: under static conditions, that buoyancy effect leads to creaming at the top of the container, but the process may be speeded up by centrifugation or filtration. The major disadvantage of the latter is the difficulty in removing the fat layer once

formed – coupled with clogging of the membrane pores – which is particularly detrimental in the case of hydrophobic matrices. Milk is often homogenized by forcing it into a tiny nozzle under high pressure, so as to reduce the average globule size to less than 1 μm ; this creates a more uniform distribution of globules that improves kinetic stability of the emulsion (Fox and McSweeney 1998).

Hydrolysis of fats can be effected by lipases (and esterases, to a lesser extent), which require a fat/water interface be present; this type of interfacial reaction is thus promoted by high specific areas, which may be attained at the expense of addition of emulsifiers and vigorous stirring. However, lipases are typically much more expensive than their fat substrates, so some form of immobilization thereof is in order for economic feasibility; this approach is particularly simple because such enzymes do not require cofactors for catalytic activity, while possessing a relatively high hydrophobic nature that facilitates spontaneous adhesion to hydrophobic materials via adsorption.

Several immobilized microbial lipases are available from industrial suppliers, using, e.g., ion exchange resins and polymeric materials as supports; they have been applied to hydrolyze fats in emulsified form, but show the disadvantage that the fat and enzyme particles must collide for catalysis to occur. Porous membranes constitute an interesting alternative, because lipase can be immobilized inside their pores – with water pumped along one side and (melted) fat along the other. Besides low rates of fouling, said tangential membranes may offer high volumetric efficiencies – especially if they are manufactured in hollow-fiber form – and permit the concentration of fat to remain at its maximum level ever by circumventing phase mixing.

Furthermore, immobilized lipase processes offer fatty acid- and stereo-specificity advantages over plain acid- or base-catalyzed hydrolysis of fats – which are intrinsically nonspecific. Considering the difference in metabolism of fatty acids depending on their original regiodistribution and chain length, lipases have been largely applied to produce tailor-made derivatives of triacylglycerols with medium- or short-chain fatty acid residues in external positions (*sn*-1 and *sn*-3) and long-chain fatty acids in the internal position (*sn*-2) (Willis

et al. 1998); these are in higher and higher demand for nutritional purposes.

Depending on the level of water in their vicinity, membrane-immobilized lipases operating on a fat substrate may also perform ester synthesis, as well as interesterification – of the acidolysis, alcoholysis, and transesterification types – depending on whether the aqueous substrate is replaced by a fatty acid, an alcohol, or another fat, respectively. This process is relatively easy to bring about, but suffers from two major shortcomings: enzymes tend to deactivate as time online elapses, thus calling for enzyme makeup; and product separation is often difficult, especially when only lipid phases are involved – and resorts to distillation (which should be carried out at low pressure in the case of heat-labile fats).

Fat Processing, Membrane Operations of

Angela C. Macedo¹ and F. Xavier Malcata²

¹LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

²DEQ – Department of Chemical Engineering and LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

Fat processing is an active business, designed to create added value from slaughter by-products downstream the animal chain. It encompasses activities dealing with production of animal fats (and proteins) suitable for human consumption in agreement with directive 77/99/EEC (EU 1997),

as well as processing of category 3 (formerly labeled low risk) materials from animals approved for human consumption in agreement with regulation ABPR 1774/2002/EC (EU 2002). Fat processing has historically been associated with manufacture of high-grade animal fats for specific markets, e.g., bakery industry, calf milk replacers, and pet food – as well as commodities for formulation in the oleo-chemical industry (e.g., manufacture of soaps) and cosmetics; it uses bovine tallow, porcine lard, and poultry fat as major feedstocks.

The basic operations in fat processing are wet melting and dry rendering – or hybrid systems thereof. Fat tissues are subjected to relatively mild processing conditions to minimize their decay – but high-quality final products hinge critically on the quality and source of the raw materials. They are usually collected from slaughterhouses from animals slaughtered on the same day and undergo strict food safety steps according to HACCP methodology – including monitoring of environmental contaminants, growth hormones, and veterinary drugs. Membrane processing is possible, but only on clean melted fat – and chiefly to deliver support for enzymes aimed at controlled chemical modifications of such fat, e.g., interesterification.

Fat interesterification can be carried out via chemical or enzymatic processes; the former require metal alkalis as catalysts, but produce random interchange of acyl groups, lead to contamination of the final product with residual catalyst, and allow formation of soaps – all of which are viewed as drawbacks relative to their enzymatic counterparts (Erickson 1995). Lipase-mediated interesterification with lipases is characterized by great versatility, reasonable substrate selectivity (including regio- and enantioselectivity), possibility of operation at room temperature and pressure, and the absence of side reactions. To fully exploit the technical advantages of such enzymes, economic feasibility recommends the use in immobilized form – to extend their useful life, avoid product contamination and consequent instability, and circumvent the need for emulsification (James et al. 2009). Lipase immobilization also facilitates product separation,

enhances thermostability, alleviates rate dependence on pH, and is more flexible in terms of reactor configuration.

Unlike hydrolases at large that operate in plain aqueous phases, lipases are activated only in the presence of water/lipid interfaces – provided by the contacting surface between the immiscible aqueous and fat phases, which can be made to coincide with a porous membrane. Techniques that met with industrial success for immobilization of lipases include adsorption, covalent binding, and entrapment/microencapsulation (Knezevic et al. 2004). Note that the economic feasibility is directly related to the volumetric productivity on the long run, which depends in turn not only on the operational stability of the enzyme but also on its actual activity – which is normally lower than that of free enzyme, in addition to mass transfer constraints (Vulfson 1994).

Physical adsorption is the simplest method for lipase immobilization; binding occurs via hydrogen bonds, salt linkages, and van der Waals forces. The process is carried out at mild conditions, without (or with a marginal) support activation and in the absence of extraneous reagents; it is thus prone to preserving enzyme activity and specificity. The chemical nature of the carrier (including the ratio of hydrophilic to hydrophobic groups), the particle size and porosity, and the surface area available determine the amount of enzyme bound, as well as the enzyme behavior following immobilization (Cao 2005).

Chemical reaction between activated amino acid residues far from the catalytic and binding site of the enzyme and active functionalities on the carrier is the basis of (effective) covalent attachment. This is clearly the most efficient mode of immobilization – despite its being much more detrimental for enzyme activity, complex in terms of implementation, and heavily dependent on the properties of the carrier (Cao 2005).

Finally, entrapment involves capture of enzyme within a polymeric matrix during the polymerization process – whereas (the related) microencapsulation entails confinement by a membrane-like physical barrier around the enzyme preparation; entrapped enzymes may be further microencapsulated. Both processes require

simple equipment and relatively inexpensive reagents – and yield a better stability and an activity similar to adsorbed enzymes (Cao 2005).

Faujasite

Anne Julbe and Martin Drobek
Institut Européen des Membranes, Université de Montpellier, Montpellier, France

FAU (faujasite) belongs to the family of aluminosilicate molecular sieves defined by the formula $[(Ca, Mg, Na)_29(H_2O)_{240}[Al_{58}Si_{134}O_{384}] - FAU$ (www.iza-online.org). Two types of synthetic FAU zeolites referenced as Linde X and Linde Y differ in Si/Al atomic ratio, which is typically in the range from 1 to 1.5, one to two for the X and higher for the Y zeolite. The 24-tetrahedra cuboctahedral units (sodalite cages) in the FAU framework type are connected via hexagonal prisms (double six-rings) forming a three-dimensional porous channel structure along [110]. These are characterized by 12-oxygen ring

Faujasite, Fig. 1 The FAU-type zeolite supercage – view along [111] direction (International Zeolite Association (IZA))

window openings with the aperture of 8 Å and supercages of approximately 12 Å (McCusker and Baerlocher 2001). The FAU-type zeolite supercage viewed along [111] is shown in Fig. 1 (International Zeolite Association (IZA)).

The combination of large void volume and large pore openings in a three-dimensional channel system makes FAU thermally stable molecular sieve ideal for many catalytic, ion-exchange, and adsorption applications. FAU zeolites are generally synthesized by hydrothermal crystallization of reactive alkali metal aluminosilicate gels or clear solutions at low temperatures (70–300 °C, usually 100 °C) and pressure (autogenous) under alkaline conditions. Starting typically from sodium aluminate and sodium silicate, the zeolite is obtained in its Na^+ form (Blatter and Schumacher 1991). Replacement of the Na^+ cations by protons (leading to the H-zeolite form) is required for applications in acid catalysis. In addition, for specific catalytic applications, incorporation of various metal cations into the structure is carried out by impregnation or ion exchange and results in modification of the number and nature of acid sites influencing the diffusion of reactants and products. X-type zeolite has a wide range of industrial applications for gas or vapor adsorption, separation, and as catalyst (isomerization of

1-butene, alkylation of toluene with ethylene or methanol, cycloaddition of carbon dioxide to ethylene oxide (Ribeiro et al. 1984)). However, in many large-scale industrial applications, its chemical analogue with Si/Al ratio higher than 1.5 (zeolite Y) has superseded zeolite X because of its higher chemical and thermal stability. USY (ultra-stable Y zeolite prepared by dealumination of zeolite Y) is one of the most widely employed zeolitic materials in the petrochemical industry, essentially as a fluid cracking catalyst (FCC) of heavy petroleum distillates, for increasing the yield of gasoline and diesel fuel from crude oil. Considering membrane applications, the production of tubular FAU zeolite membranes has been mainly considered for alcohol dehydration by vapor permeation (Sato et al. 2008).

Feed Pressure

Giuseppe Barbieri
Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane operations, for instance, membrane reactors, membrane gas separators, membrane contactors, membrane emulsifiers, membrane

crystallizers, reverse osmosis, nanofiltration, ultrafiltration, microfiltration, etc. as well the more conventional unit operations, like reactors, distillation columns, adsorbers, absorbers, liquid-liquid extractors, filters, pipelines, etc., are fed by a stream entering the unit. The pressure of this stream (to be treated by the unit operation) at the entering section of each unit operation is defined as feed pressure.

A further specification is required for membrane systems. Often, an auxiliary stream named “sweep” is fed to the membrane unit. This stream is characterized by a different pressure named “sweep pressure”; this pressure cannot be referred to as “feed pressure.”

Fenton Test

P. Knauth
Madirel UMR 7246, Aix Marseille University-CNRS, Marseille Cedex, France

Fenton’s reagent was developed in the 1890s by Henry John Horstman Fenton as an analytical reagent (Fenton and Jones 1900). It is a solution of hydrogen peroxide and an iron catalyst. Iron (II) sulfate is a typical iron compound in Fenton’s reagent.

The mechanism mostly accepted today, suggested by Haber and Weiss in the 1930s (Haber and Weiss 1932), is that iron(II) is oxidized by hydrogen peroxide to iron(III), a hydroxyl radical and a hydroxide anion (reaction 1):

Iron(III) is then reduced back to iron(II), a peroxide radical and a proton by the same hydrogen peroxide (dismutation reaction 2):

In the overall reaction, two molecules of hydrogen peroxide are converted into two radicals and water by the presence of catalytic iron ions.

The free radicals generated by Fenton's reagent induce then secondary reactions: the free hydroxyl radical is a powerful, non-selective oxidant used to oxidize organic contaminants in waste waters to primarily carbon dioxide and water.

Nowadays, Fenton's test is applied for the accelerated testing of the oxidation stability of proton exchange membranes (PEM) for fuel cell applications (Healy et al. 2005). Generally, the weight loss after a defined treatment time is used to monitor membrane degradation. Typical Fenton's test conditions for PEM membranes are an aqueous solution with 30 % H_2O_2 and 20 ppm Fe^{2+} at 80–90 °C with three treatment cycles with fresh reagent and 24 h per cycle. Given that the initial H_2O_2 concentration is much higher than in an operating fuel cell, "softer" alternative conditions are also used with an aqueous 3 % H_2O_2 solution mixed with 4 ppm Fe^{2+} at 68 °C (Ramaswamy et al. 2008).

Although Fenton's test is straightforward and considered as a benchmark for PEM evaluation, it has inherent limitations, given that the membrane degradation in this test is not related to an electrode process and does not involve variations in fuel cell operating conditions, e.g., operating potential, relative humidity, and the presence of fuel and oxygen.

Fiber Models

Vasilis Burganos

Institute of Chemical Engineering Sciences,
Foundation for Research and Technology –
Hellas, FORTH/ICE-HT, Patras, Hellas

A fiber model is a model that uses straight or curved fibers, either finite in length or infinitely long, to represent the solid phase in a porous material or a reinforcement component in a composite material. Fiber models are the appropriate choice for modeling fibrous media, woven or non-woven, typically synthetic but occasionally also natural ones. Typical examples include the representation of membranes and porous media for fuel cells (Mathias et al. 2003), filters for the separation or sieving of particulate matter, or filters for the exclusion of bubbles in diverse applications of microfluidics. There is a recent rapid growth of interest in the utilization of fiber models for the description of the structure of gas diffusion layers in fuel cells but also of modern textiles and fabrics for specialized applications (Thiedmann et al. 2009; Gaiselmann et al. 2012). The typical features that characterize a fiber model include the diameter and length of the fiber, the number or length density per unit volume, the solid fraction, the shape of the fibers, and the elastic properties of the fibers that determine the macroscopic mechanical properties of the material. Carbon cloth, electrospun polyacrylonitrile, and polyester are common examples of fibrous materials that can be represented by fiber models. To convert to a pore model, various attempts have been made to infer some effective pore sizes from the fiber model, usually with the help of inscribed spheres among neighboring fiber segments. Skeletonization of a fiber model is often part of the analysis routine to facilitate the comprehension of the fiber cluster articulation and the eventual determination of the topology of the system. Useful concepts from straight-line path statistics or randomness of secant distribution through convex bodies (Coleman 1969) are incorporated in this type of models. The fibers can be hollow or

solid, randomly oriented or ordered to arbitrary degree, and either charged or neutral depending on the application. Fiber models of membrane materials and, more generally, fibrous media lend themselves to the numerical simulation of transport phenomena through their structure, usually diffusion, single or, two-phase flow, dispersion, particle attraction and deposition, combined phase transition and flow, heat conduction, electrical conduction, and light transmission (Torquato 2002; Tomadakis and Sotirchos 1993).

FIB-SEM Tomography

Gonzalo Prieto
Max-Planck-Institut für Kohlenforschung,
Mülheim an der Ruhr, Germany

FIB-SEM tomography (also known as tomographic FIB-SEM) is a micrometer-to-nanometer scale imaging technique which combines a focused ion beam (FIB) (Yao 2007) with a scanning electron microscope (SEM) (Goldstein et al. 2003) to obtain information on the internal structure of solid specimens. Focused ion beams

were developed in the early 1970s as a tool to either etch or deposit material on solids with (sub-) micrometer precision, via either volatilization or deposition processes, respectively, assisted by a beam of ions. They soon became an essential micromachining tool in the semiconductor industry. Later, the FIB technology was integrated into SEM devices. Such combination enables direct imaging of those solid surfaces previously processed with the FIB via detection of either backscattered or secondary electrons. A FIB-SEM device comprises a built-in FIB gun and a SEM detector, typically oriented forming an angle of 52–55°. Advances in FIB resolution and automation have paved the way to FIB-SEM tomography. *Tomography*, from Ancient Greek terms *tomos* (slice) and *grapho* (to write, to record), refers to the possibility of reconstructing the three-dimensional structure of an object, or a selected internal plane, by gathering information on discrete thin slices or two-dimensional projections of said object.

In a typical FIB-SEM tomography experiment, the specimen, often embedded in a resin, is situated at the coincident point of the FIB and SEM beams. Generally, solid specimens are previously sputtered with metal overlays to protect the sample surface during FIB milling and to increase its conductivity, in the case of specimens with insufficient electrical conductivity, thereby preventing charging effects in the course of the experiment. A trench is first carved on the upper surface of the sample with the FIB. Then several cross-sections of the internal structure of the specimen, exposed upon sequential erosion of thin layers with the FIB, are consecutively imaged with the SEM. Figure 1a depicts schematically the working principle of the serial milling and imaging procedure in FIB-SEM tomography.

The outcome is a stack of SEM micrographs of the consecutive cross-sections, which after alignment and further processing serves to reconstruct the investigated volume in three dimensions (tomogram). Typically, sample volumes in the range of 1–50 μm^3 are studied in a single FIB-SEM experiment. 3D imaging resolutions down to 10–30 nm can be achieved with modern equipments, being the limiting factor the resolution in the *z*-direction, i.e., the FIB-milling

FIB-SEM Tomography, Fig. 1 (a) Schematic representation of the alternating FIB-milling and SEM-imaging during a FIB-SEM tomography experiment on a membrane specimen. (b) 3D, surface-rendered view of a reconstructed FIB-SEM tomogram of a mixed-matrix

membrane incorporating metal-organic-framework (MOF) crystals within a polymer matrix. MOF particles are depicted in *green*, membrane void defects are shown in *red*, while the polymer matrix is depicted transparent (Rodenas n.d.)

direction. Such resolution closes the gap between other three-dimensional imaging methods such as electron tomography, which relies on transmitted electrons, and techniques based on X-rays such as X-ray tomography. As a result of the detailed and three-dimensional information provided on the internal structure of a wide array of solid specimens, FIB-SEM tomography has become an outstanding tool in a number of scientific and technological disciplines, including life-, earth-, and materials science.

Due to the typical sizes of membrane pores, ranging from nanometers to hundreds of micrometers, the resolution of this technique is suitable to study the internal porosity of a broad array of technologically relevant membranes, including analysis of different layer components in asymmetric membranes. In addition, the information gathered in FIB-SEM tomograms can be interpreted on a quantitative basis by combination with suitable image analysis methods (Haidekker 2011). In multicomponent membranes, FIB-SEM tomography enables assessing the proportion, degree of integration, and relative spatial location of different internal elements in three dimensions. As an example, Fig. 1b depicts a reconstructed FIB-SEM tomogram of a mixed-matrix membrane incorporating metal-organic-framework crystals within a polymer matrix. Three-dimensional visualization can also be applied to

image the most common membrane defects such as pinholes, cracks, or voids. In this respect, FIB milling represents an advanced solution to expose membrane cross-sections for imaging, as compared to more conventional approaches such as fracturing at cryogenic temperatures, which are prone to introduce a number of artifacts in the freshly generated surface to be imaged. The aforementioned structural features are known to be of significance for key performance parameters such as selectivity and permeability. Hence, detailed visualization of internal structures with FIB-SEM tomography contributes to the design and optimization of the membrane production and processing procedures. FIB erosion can also be applied to produce thin tips or slices from thicker membrane specimens, as required to be studied with complementary three-dimensional imaging methods such as atom-probe tomography, X-ray tomography, or electron tomography.

Fick's Laws

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

Fick's laws (first and second Fick's laws). These two laws of diffusion were originally postulated by the medical doctor Adolf Eugen Fick (1829–1901) (from whom they take their name) by analogy with energy transfer in conduction and not by experiment (Fick 1855; Bird et al. 2002).

First Fick's law. For a generic species A in a mixture, first Fick's law is referred to as the constitutive equation for mass flux of A stating the proportionality between flux and mass gradient in a certain domain, which can be used in solid, liquid, and gas phase (Bird et al. 2002; Krishna and Taylor 1993). This relationship can be expressed both in term of mass (Eq. 1) and molar quantities (Eq. 2) as

$$\underline{j}_A = -\rho D_A \nabla w_A \quad (1)$$

$$\underline{J}_A = -c D_A \nabla x_A \quad (2)$$

where j_A and J_A are the mass and molar flux of the species A, respectively; ρ [kg m⁻³] is the density of mixture; c [mol m⁻³] is its total concentration; w_A [kg_A kg⁻¹] and x_A [mol_A mol⁻¹] are the mass

and molar fraction of the species A, respectively; and D_A [m² s⁻¹] is the *multicomponent* diffusion coefficient, which generally depends on temperature, pressure, and species compositions. Equations 1 and 2 are vectorial equations, as flux is a vector. The scalar versions of Eqs. 1 and 2 along a specific direction (x) are provided by Eqs. 3 and 4, respectively:

$$j_A|_x = -\rho D_A \frac{\partial w_A}{\partial x} \quad (3)$$

$$J_A|_x = -c D_A \frac{\partial x_A}{\partial x} \quad (4)$$

For anisotropic media, the diffusion coefficient depends on the diffusion direction, and thus, it is a second-order tensor (Eq. 5) rather than a scalar:

$$\underline{\underline{D}}_A = \begin{bmatrix} D_{A,xx} & D_{A,xy} & D_{A,xz} \\ D_{A,yx} & D_{A,yy} & D_{A,yz} \\ D_{A,zx} & D_{A,zy} & D_{A,zz} \end{bmatrix} \quad (5)$$

In Eq. 5, the diffusivity matrix is expressed with respect to a general reference system. In general, the multicomponent diffusion coefficient is not directly known, it being obtained, on the contrary, from the *binary* diffusion coefficients, which can be measured experimentally and for which semiempirical relationships are available in the literature. The relationship between the multicomponent diffusion coefficient and binary diffusion coefficient is extensively reported, for example, in the book of Krishna and Taylor (1993).

Second Fick's law. For a generic species A in the mixture, the mass conservation law (scalar) within a tiny control volume can be expressed both in terms of mass quantities (Eqs. 6, 7, and 8),

$$\frac{\partial(\rho_A)}{\partial t} = -(\nabla \cdot \underline{n}_A) - (\nabla \cdot \underline{j}_A) + r_A \quad (6)$$

$$\underline{n}_A = \rho_A \underline{v} \quad \rho_A = \rho w_A \quad (7)$$

$$\underline{v} = \sum_{i=1}^n w_i \underline{v}_i \quad (8)$$

and molar quantities (Eqs. 9, 10, and 11), analogously to what is reported for *first Fick's law*.

$$\frac{\partial c_A}{\partial t} = -(\nabla \cdot \underline{N}_A) - (\nabla \cdot \underline{J}_A) + R_A \quad (9)$$

$$\underline{N}_A = c_A \underline{v}^* \quad c_A = c x_A \quad (10)$$

$$\underline{v}^* = \sum_{i=1}^n x_i \underline{v}_i \quad (11)$$

where n_A and N_A are the mass and molar convective flux, r_A and R_A are the mass and molar generation terms – which can be positive (source) and negative (sink) –, and $\underline{v}_i$ is the arithmetic average of the velocities of all the molecules of the i th species in mixture within the control volume.

If there is no either net convective transport or sinks/source of mass within the control volume, Eqs. 6 and 9 are simplified to give Eqs. 12 and 13, which represent the common form of *second Fick's law*:

$$\frac{\partial(\rho_A)}{\partial t} = -(\nabla \cdot \underline{j}_A) \quad (12)$$

$$\frac{\partial(c_A)}{\partial t} = -(\nabla \cdot \underline{J}_A) \quad (13)$$

In *membrane technology*, *first Fick's law* is coupled with the second one to calculate flux and concentration profiles of the species along and through the membrane in reaction and separation processes. These are of practical interest to model the membrane behavior, to eventually optimize the operating conditions, and to maximize the process performance.

Filler in Membranes

Antonino Salvatore Arico
 CNR-ITAE Institute, Messina, Italy

Synonyms

Inorganic fillers

Composite perfluorosulfonic acid membranes containing different types of inorganic fillers such as hygroscopic oxides, surface-modified oxides, zeolites, inorganic proton conductors, etc. have shown an increased conductivity with respect to the bare perfluorosulfonic membranes at high temperature (Aricò et al. 1998, 2003). The presence of hygroscopic inorganic oxides inside the composite membrane besides extending the operation of perfluorosulfonic membranes (e.g., Nafion®) in the high-temperature range reduces the crossover effects by increasing the “tortuosity factor” in the permeation path. Such effects are particularly serious at high temperature in DMFC systems. An appropriate tailoring of the surface chemistry in these nanoparticles is a key step to enhance water retention at high temperature. Composite recast Nafion® membranes containing inorganic fillers have been employed in high-temperature (~150 °C) direct alcohol (Aricò et al. 1998) and H₂-air fuel cells (Watanabe et al. 1996). These composite membranes were originally developed for reduced humidification operation in polymer electrolyte fuel cells (Watanabe et al. 1996) due to the enhanced water retention inside the membrane by the effect of the inorganic filler (Aricò et al. 1998). A further advantage of composite membranes relies in the barrier effect given by the inorganic filler for methanol crossover (Ren et al. 1996).

Finger-Like Structure

Tao He

Lab for Membrane Materials and Separation Technology, Shanghai Advanced Research Institute CAS, Shanghai, China

Finger-like structure is one of the typical membrane structures, as shown in Fig. 1. It is also called macrovoid structure. Figure 1 shows asymmetric membranes with a thin top skin layer supported by a finger-like sublayer. Formation of finger-like structure follows two processes: pore initiation and growth. As a polymer solution undergoes a liquid-liquid phase separation, both polymer-rich and polymer-lean phases are

developed. The nuclei of the polymer-lean phases initiate the finger-like structure. The nuclei are mostly formed just beneath the top layer, and growth of the nuclei depends on the state of the solution in the frontier of the phase separation (Marcel 1996). The nuclei may grow if the polymer solution in the front is stable and could supply enough solvent (or solvent/nonsolvent) to sustain the growth. The growth ends when new nuclei are initiated in the frontier of phase separation or the concentration of the polymer-lean phases enters the glass transition point. At an extreme condition, the finger-like structure in the PSf membrane penetrates through the whole cross section because bottom PEI solution provides solvent to sustain the growth of the polymer-lean phases in the PSf layer (Xiao et al. 2015).

Finger-like structure is not strong enough for many applications due to the weak mechanical property, e.g., gas separation, nanofiltration, and reverse osmosis. Suppress of the finger-like structure is quite a scientific and artistic task for membrane scientists and engineers. Upon formation of nuclei of polymer-lean phases, if there is no solvent to sustain the growth, no finger-like structure would result. By adding a significant amount of nonsolvent into the polymer solution, it may generate simultaneously a lot of polymer-lean phase nuclei, thus preventing the polymer-lean phases from growing to full-sized finger-like macrovoid.

Finger-Like Structure, Fig. 1 Finger-like structure of a polyethersulfone flat sheet membrane. (a) Cross section of a PES ultrafiltration membrane; (b) cross section of a PSf membrane prepared by casting a PES/NMP

solution (17/83 wt.%) onto a PEI/NMP (20/80 wt.%) solution and then immersed in water for precipitation. The fingers penetrate through the membrane

Increasing the polymer viscosity may reduce the growth rate of the nuclei and allow more time for the formation of more nuclei in the front, leading to less finger-like macrovoids.

As a rule of the thumb, instantaneous demixing is generally related to the formation of a finger-like macrovoid structure. Therefore, by adding a solvent into the coagulation bath, choosing a solvent/nonsolvent (as the coagulant) system with low affinity is common practice to suppress the finger-like structure. For a certain solvent/nonsolvent pair, the hydrophobicity of the polymer is also crucial. For polar solvent/nonsolvent systems, e.g., NMP/H₂O, DMAc/H₂O, and DMF/H₂O, a PVDF/solvent solution will end up with a sponge-like structure due to the strong hydrophobicity of the polymer in nonsolvent-induced phase separation using water as the coagulant. However, by adding hydrophilic polymer additive into the PVDF solution, finger-like macrovoids are generated. Encouraging delayed demixing is key to prevent the finger-like structure, because onset of the nuclei is delayed and the top skin layer is densified. However, this is often unfavorable for membrane performance.

Fixed Bed Catalytic Reactor

Fausto Gallucci
Chemical Process Intensification, Department of
Chemical Engineering and Chemistry, Eindhoven
University of Technology, Eindhoven,
The Netherlands

The fixed bed (or packed bed) membrane reactor configuration is the first and most studied configuration for membrane reactors. This is because the

first studies on membrane reactors focused on the effect of the gas permeation through membranes on the reaction system (which is often a conventional packed bed reactor).

In a packed bed membrane reactor, the catalyst is confined in fixed bed configuration, and it is in contact with a permselective membrane. The most used packed bed configuration is the tubular one where the catalyst may be packed either in the membrane tube or in the shell side, while the permeation stream is collected in the other side of the membrane (in the case of hydrogen-selective membranes) or one reactant is feed on the other side of the membrane (in the case of oxygen-selective membrane).

For multitubular membrane reactor configurations, the catalyst in tube configuration can be preferred especially for construction reason and for the extent of bed-to-wall mass and heat transfer limitations which can be very detrimental in the catalyst in shell configuration.

Often, a sweep gas can be used in the permeation side of the membrane in order to keep the permeation hydrogen partial pressure as low as possible for minimizing the membrane area required for the hydrogen separation. This practice is, for example, very useful if hydrogen for ammonia plant is being produced, in which case an amount of nitrogen can be used for sweeping the permeation side producing a synthesis stream ($N_2/H_2 = 1/3$) ready for the final reaction step. If a sweep gas is used in the permeation side, then a packed bed membrane reactor can be used in both cocurrent or countercurrent modes.

An interesting feature of packed bed membrane reactors is the possibility to operate them in a reverse flow mode, integrating the reaction and separation with the recuperative heat exchange inside the reactor. This operational mode is quite interesting for partial oxidation of methane (POM) (Smit et al. 2005). In normal POM systems air and CH₄ feed streams have to be preheated to the reaction temperature, while being POM reaction only slightly exothermic, the external heat transfer between feed and exhaust is very expensive. Therefore, recuperative heat exchange is preferably carried out inside the reactor.

Although the tube in tube configuration is quite useful to work in lab scale and for proof of principle of membrane reactors, for industrial scale some other configurations need to be used in order to increase the membrane area per volume of vessel used. In fact, the amount of hydrogen produced is directly related to the amount of membrane area installed in the reactor. Starting for the tube in tube configuration, a straightforward way to increase the membrane area in packed bed is the tube in shell configuration (Buxbaum 2002; Tosti et al. 2008).

Although the packed bed configuration is very advantageous and easy to operate, the production of thin membranes brought under the spotlight one of the disadvantages of fixed bed membrane reactors: the influence of bed-to-wall mass transfer limitations on the membrane area required. Briefly, as long as the hydrogen flux through the membrane is a limiting step, the effect of external mass transfer limitations such as the limitations to hydrogen transport between the bulk of the catalytic bed (where hydrogen is produced) and the membrane wall (where hydrogen is recovered) can be neglected. However, by increasing the membrane flux, the external mass transfer limitations became limiting and determine the extent of membrane area. This has been demonstrated both experimentally (Peters et al. 2008) and numerically (Gallucci et al. 2010). This important drawback has driven the research toward new reactor concepts such as micro-membrane reactors or fluidized bed membrane reactors.

Fixed Carrier Membrane

Marius Sandru

Polymer Particles and Surface Chemistry,
Materials and Chemistry, SINTEF, Trondheim,
Norway

Fixed (site) carrier membranes (FSC) combine the durability of a dense membrane with the selectivity of a supported liquid membrane (SLM) overcoming the limitation of SLM, degradation due to the wash out of the carrier solution over time. The carrier is either covalently bonded to the polymer chain (chained carrier) or immobilized in the polymer matrix by physical constraints or weaker ionic bonding. A fixed carrier membrane will separate mainly via facilitated transport mechanism, implying that the carrier will react specifically with one of the components to be separated.

Noble (1990, 1991) and Cussler (Cussler et al. 1989) developed two different models to describe the transport across fixed carrier membranes. E. L. Cussler explained the transport by “chained carrier” theory, when carriers are covalently bonded, requiring a certain mobility of polymeric chains and that a percolation threshold appears when two chained carriers are too far apart.

R. Noble described the transport of neutral molecules such as O₂ (Noble 1990) or ions (Noble 1991) across membranes in the terms dual-mode sorption model, assuming the presence of two distinct regions exhibiting gas solubility based on Henry’s law and Langmuir sorption isotherm. The model assumes also that permeation is diffusion-limited. This model shows the same behavior as facilitated transport in liquid membranes and does not predict a percolation threshold as “chained carrier” model does. The model implies that the

effective diffusion coefficient of the solute to be transported depends on the morphology of membrane between two reactive sites (“terrain”). Changes in polymer morphology cause a change in this effective diffusion coefficient.

The model presented by R. Noble is based on the model presented by Barrer (1984) assuming that a hole (microvoid) of the polymer free volume is equivalent to a complexing site (a carrier). Barrer’s dual-mode transport for glassy polymers contains four diffusion coefficients: diffusion of a compound (A) through the polymer matrix, diffusion of (A) from the polymer matrix to a hole in the Langmuir region (excess of free volume), diffusion of (A) between two holes, and diffusion of (A) from a hole to the polymer matrix. The significance of this analysis is that it predicts facilitated transport even when there is no diffusion or mobility of the complexing agent.

Both Noble’s and Cussler’s models have their limitations. Dual sorption model presented by Noble assumes that the concentration of the carrier is in large excess and consequently constant. This implies that the model will start to deviate from experimental results at high loadings of the carrier with the permeant (A) (carrier saturation). Also the model does not take into account the reaction kinetic between the carrier and permeant (A).

The hopping mechanism proposed by Cussler will strongly depend on the system permeant-membrane material characteristics even though it is taking into account the chemical reaction between the carrier and component (A): high diffusion coefficients of a compound (A) will allow facilitation effect even at low concentration of the carrier infirming a strict percolation threshold predicted by the model.

Fixed-Site (Chained-Carrier) Membranes

Marius Sandru

Polymer Particles and Surface Chemistry,
Materials and Chemistry, SINTEF, Trondheim,
Norway

Carrier-facilitated transport processes in liquid membranes often achieve spectacular separations between closely related species because of carrier selectivity. The instability of supported liquid membranes (SLM) or emulsion type of membranes (ELM) is a major technical challenge for their implementation at large industrial scale (Mulder 2003; Baker 2004; Koros and Mahajan 2000). One approach to stabilize the membranes is to covalently link the carrier complex to the matrix polymer resulting in fixed-site carrier (chained) membranes.

The term *chained carrier* refers to transport mechanism theory rather than to position of the carrier on the membrane. E. L. Cussler (Cussler et al. 1989) explained the *facilitated transport* by a “chained carrier” theory that implies a certain mobility of polymeric chains and that a percolation threshold appears when two chained carriers are too far apart. Chained carriers, by comparison to mobile carriers diffusing freely within a liquid membrane, have limited diffusion because they are covalently bound in the polymer membrane. The solute is transported via a hopping (“Tarzan”) mechanism from one carrier to the next one between the two interfaces, feed and permeate sides of the membrane.

In order to transport components via facilitated transport, the polymeric chains must have a certain mobility degree, and the concentration of the carrier must be higher than the percolation threshold (Cussler et al. 1989).

The hopping mechanism proposed by Cussler will strongly depend on the system permeant-membrane material characteristics even though it is taking into account the chemical reaction between the carrier and a component (A): high diffusion coefficients of a compound (A) will allow facilitation effect even at low concentration of the carrier infirming a strict percolation threshold predicted by the model.

A particular case of “chained carrier” for CO₂ transport is presented by KT.J. Kim et al. (2013). The carrier is represented by the amine groups covalently bonded to the polymeric chain of polyvinylamine.

Flat Sheet Membrane Module

► Cross-Flow Membrane Module

Flat Sheet Membrane Photocatalytic Reactor

Raffaele Molinari
Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

When membrane configuration is flat type and it is coupled to a photocatalytic reaction, the reactor can be named flat-sheet membrane photocatalytic reactor.

A recirculation cell containing various types of flat-sheet membranes which were able to retain the suspended catalyst and partially selective to the pollutant was studied by Molinari et al. (2001). The membranes were NTR7410 and NTR7450 (Nitto Denko), N30F and NF-PES-010 (Hoechst), and MPCB0000R98 (SEPAREM). The measured permeate flux was in the range 5–30 l/h m² at 4 bar, and all membranes showed both a rejection and a capacity to adsorb the pollutant with a transitory phase varying from 80 to 400 min at 4 bar. This behavior could be a benefit for the process because oscillations in the pollutant concentration were not transmitted in the permeate. Three factors, rejection, photocatalytic degradation, and adsorption, were able to maintain the 4-nitrophenol (4NP) concentration in the permeate at very low values. For the continuous system, the lowest 4NP concentration in the permeate was 6–7 % (w/w) of the initial 4NP concentration (40 mg/l) after a transient period of 300 min.

In another method, the catalyst, TiO₂ P25 Degussa, was immobilized by physical deposition on a flat-sheet polymeric membrane, and 4NP was used as a model molecule to evaluate the reactor performance (Molinari et al. 2000). A preliminary investigation of the stability, under UV irradiation, of some eligible polymeric membranes was carried out by using scanning electron microscopy (SEM), optical microscopy (OM), determinations of water permeation flux (WPF), and total organic carbon (TOC). These tests showed that commercial membranes made of fluoride + PP (FS 50 PP-Dow), polysulfone + PP (GR 51 PP-TechSep), and polyacrylonitrile (PAN-TechSep) seemed to be quite stable to UV light over a 24 h period of irradiation. Immobilization of TiO₂ onto membranes by ultrafiltrating TiO₂ suspensions showed an optimal layer density slightly >2.04 mg TiO₂ per cm² of membrane surface area. Results obtained from membrane reactor studies indicated that the observed initial rate constants for the degradation of 4NP were almost independent on the amount of TiO₂ employed over the range 0.76–4.08 mg/cm². A 50 % weight degradation of 4NP after 5 h of irradiation in the presence of air was obtained. An

almost complete degradation of 4NP, instead, was observed in the presence of TiO_2 suspended in the solution and pure oxygen. The permeate deriving from the membrane photoreactor was clear, and 4NP concentration was approximately equal to that found in the retentate. The possibility of the continuous reuse of the photocatalyst and the continuous separation of products from the reaction medium gave some advantages over traditional approaches.

A flat-sheet membrane photocatalytic reactor operates, generally, with suspended solids (the catalyst) and air bubbling (oxygen feed), so, in the following, some cases of interest for operating such reactors are reported.

Selection of a membrane configuration is a crucial step in the design process and has a high impact on further plant operations. Despite increasing experience with full-scale applications, practical knowledge concerning the impact of different membrane configurations on process performance and operational costs is still lacking. Full-scale performance data of a membrane bioreactor (MBR) comparing the use of flat-sheet and hollow-fiber membranes and analyses of the consequences on operation, performance, and treatment efficiency have been reported by Krzeminski et al. (2012). Hollow-fiber configurations, compared to the flat sheet, are designed for higher fluxes, operated at lower concentrations, cleaned more often, and protected by stricter pretreatment. Filterability of activated sludge from municipal MBRs was better than from industrial MBRs and did not depend on membrane configuration. The energy consumption depends more on the influent type than on the membrane configuration.

An aerated flat-sheet module focusing on the effect of bubble distribution on the spatial variation of surface mass transfer with intermittent slug bubbling was studied by Field et al. (2011). This mode of operation will delay the onset of the transmembrane pressure jump if biomass removal is more dependent upon maximum shear stress than mean shear stress. Two basic setups were considered: an orifice in the middle of the aeration tube, at the base, and two symmetrically placed orifices in the aeration tube. With relatively low

air rates, a single orifice generates a higher average enhancement than two orifices, but the reverse was found at a relatively higher air rate. The enhancement in the center area of the module was relatively higher than that of the edge regions when using a single orifice, but more uniformity was achieved with two.

Exploration of two major commercialized flat-sheet and hollow-fiber membranes in a submerged membrane fungi reactor fed with a synthetic textile wastewater revealed striking differences in the extent and mechanism of fouling between the two types, indicating a case-specific scope of choice between them for industrial wastewater treatment (Hai et al. 2005). The hollow-fiber membrane exhibited fouling with a cake layer composed of fungi and starch, intensity being proportional to the operating flux (0.05–0.3 m/d). Conversely, the flat-sheet membrane suffered from immediate internal pore blocking beyond a critical flux of $0.2 \text{ m}^3 \text{ m}^{-2} \text{ d}^{-1}$. During the experiment with major constituents of the synthetic wastewater separately, while media containing only starch and only dye induced negligible fouling, flux-dependent pore blocking was evident for both the hollow-fiber ($0.288 \text{ m}^3 \text{ m}^{-2} \text{ d}^{-1}$) and flat-sheet membranes ($1.3 \text{ m}^3 \text{ m}^{-2} \text{ d}^{-1}$) for the mixture of starch and dye. Despite that a remarkable 99 % color and 97 % TOC removal were achieved by both membranes, fouling with different modes and intensity for the two types under similar conditions and for the same type of membrane under different exposure conditions warrants development of suitable modules for such recalcitrant wastewater.

The oxygen transfer across a microporous, flat-sheet membrane with and without a nitrifying membrane-aerated biofilm (MAB) was studied by Shanahan and Semmens (2006). Clean membrane oxygen transfer was quantified via average mass transfer coefficients and local fluxes calculated from profiles of dissolved oxygen (DO) along the membrane length. Stoichiometric calculations and DO profiles were used to characterize oxygen transfer with a nitrifying MAB. Comparison of the local fluxes with clean and biofilm-coated membranes revealed that oxygen transfer was decreased in upstream sections of the membrane during cultivation of an

MAB due to reduced advection and/or turbulence near the membrane surface. By contrast, oxygen transfer was increased in downstream sections of the membrane via bacterial respiration. Oxygen fluxes generally decreased in the downstream direction with biofilm-coated membranes; however, variability in biofilm structure and membrane coverage altered this trend on several occasions. Furthermore, biofilm structures were observed to form via sloughing and settling of biomass at the membrane surface. Thus membrane configuration may have a significant influence on oxygen transfer rates in membrane reactors.

Flavanoids Separation

Beatriz Mello

UFSCar, Federal University of Sao Carlos, Buri, SP, Brazil

Flavonoids are a water-soluble class of polyphenols derived from plant secondary metabolites through the condensation of cinnamic acid with

malonyl-CoA groups (Bloor 2001). This conversion can lead to the formation of flavones, isoflavones, flavonols, and anthocyanins. Flavanoid chemical structures are based on a C6-C3-C6 skeleton that differs among each other by the saturation of heteroatomic ring C (Stobiecki and Kachilicki 2006). Further reactions as glycosilation, acylation, and alkylation cause the formation of a huge variety of flavonoids in the plant kingdom. The flavonoids consist of six major subgroups: chalcone, flavone, flavonol, flavanone, anthocyanins, and isoflavonoids. Examples of some of these subgroups are shown in Fig. 1. Together with carotenes, flavanoids are also responsible for the coloring of fruits, vegetables, and herbs. For analysis purposes, there is basically a flavonoids division into glycosides, aglycones, and anthocyanins. Each of these types is quantified by different analytical methods. The most important dietary sources are fruits, tea, and soybean. Green and black tea contains about 25 % flavonoids. Other important sources of flavonoids are apple (quercetin) and citrus fruits (rutin and hesperidin). Flavonoids are becoming very popular because they have many health-promoting effects. Some of the activities attributed to flavonoids include antiallergic, anticancer, antioxidant, anti-inflammatory, and antiviral activities.

Essential to the study of flavonoids is having the means available for their separation (analytical and preparative) and isolation. Thin-layer chromatography is a rapid, simple, and versatile method for fractionation flavonoids. However, this method has been substituted to qualitative and quantitative applications of high-performance liquid chromatography (HPLC). In HPLC analysis, flavonoids can be separated, quantified, and identified in only one operation by coupling HPLC to ultraviolet (UV), mass, or nuclear magnetic resonance (NMR) detectors. Another technique that has been gaining attention is capillary electrophoresis (CE). All the methods use the effects of the presence of the flavonoid phenyl ring which is an excellent chromophore and is responsible for the easy detection of flavonoids. Their UV spectra provide enough

Flavonoids Separation,

Fig. 1 Examples of some flavonoids. (a) quercetin – flavonol, (b) cyanidin – anthocyanin, (c) hesperidin – flavanone

information to distinguish the type of phenol (Marston and Hostettmann 2006).

Flavonoids can be also separated from each other by the use of a polymeric membrane. A relatively high concentration of polyphenolics and flavonoids present in the juices were fractionated by various methods including ultrafiltration to get a retentate that showed very high oxygen radical absorbance capacity (ORAC) even at 50 % recovery of thin juice (Kumar 2006). Membrane-based processes are usually more energy efficient than distillation, adsorption, and chromatography. Furthermore, membranes have the advantage of compatibility with a wide range of solvents and chemical products, ability to process thermally sensitive compounds, easy amenability to automation, smaller footprint, and seamless scale-up. These advantages open up several possibilities of membrane application in the production of bioactive compounds through preconcentration of dilute solutions, fractionation of a complex mixture, recovery of intermediates, and recycling of solvents. However, it is also important to be aware of the membrane-based separation drawbacks, such as limited selectivity, fouling leading to performance decline, cleaning, and higher capital costs in certain installations.

Flexibility in Gas Separation

Adele Brunetti

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The flexibility (also called easy of expansion) is the ability to operate under variable feed quality conditions, either on a short-term or long-term basis (Miller and Stöcker 1989; Brunetti

et al. 2010). The changes in feed composition occur very often in refinery applications, particularly when the source of the feed is a catalytic process or when the feedstock to the upstream unit changes as well as in flue gas streams.

In membrane processes, the increase in feed impurity concentrations tend to cause a decrease in product purity, which, however, can be maintained for small feed composition changes by adjusting the feed-to-permeate pressure ratio. In most refinery membrane applications, however, the major product impurity is methane and this can be allowed to increase slightly in the product without major downstream impact. The flue gas stream contains an amount of CO₂ ranging from 5 % to 35 % depending on the process, the rest being mainly nitrogen and few percentage of oxygen. Whether the CO₂ concentration is always higher than 20 %, the membrane systems can be considered highly flexible. On the contrary, for CO₂ concentration lower than 20 % the membrane operation offers a very low flexibility. A further reduction in CO₂ concentration, in fact, produces a reduction of the driving force with a consequent decrease in CO₂ recovery and in product purity.

The response time of membrane systems is essentially instantaneous and corrective action has immediate results. The start-up time required by the process is extremely short.

The flexibility of the absorption process is moderate. This system, in fact, responds quite well to the changes in the feed composition; however, significant differences in the fraction of the desired specie contained in the feed imply higher solvent flow rate that is strictly related to the size of equipment apart from the absorber. Furthermore, the fact that the feed stream contains oxidizing compounds (oxygen or sulfur dioxide) induces major problems of amine deactivation and promotes corrosion.

The PSA process shows a great ability to maintain purity and recovery under changing conditions. The process is self-compensating and even relatively large changes in feed impurity concentrations have little impact on performance. As the concentration of a feed impurity increases, its partial pressure increases, increasing also the amount of the impurity which will be adsorbed.

The purity can be maintained constant by a simple cycle time adjustment. The response time to variations is rapid but not abrupt, generally requiring 5–15 min for responding to a step change in feed quality. The new steady-state upon restart following shutdown is reached in about 1 h.

The cryogenic process has very low flexibility because changes in the concentration of the lower boiling components of the feed affect the product purity directly. Recovery is not strongly affected. Response time is not as rapid as for PSA or membrane systems. Start-up is 8–24 h depending on the procedure used.

Fluidized Bed Membrane Reactors

Fausto Gallucci

Chemical Process Intensification, Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

A fluidized bed membrane reactor, also indicated as membrane-assisted fluidized bed (MAFBR), is an integrated reactor where membranes (in form of tubes, hollow fibers, or planar modules) are immersed in a fluidized bed of catalyst particles. Typical example of MAFBR for hydrogen production is reported in (Gallucci et al. 2010a) and consists in a bundle of hydrogen-selective membranes immersed in a catalytic bed operated in bubbling regime. The use of fluidized bed membrane reactors makes possible the reduction of bed-to-wall mass transfer limitations, but also allows operating the reactor at a virtually

isothermal condition (due to the movement of catalyst). This possibility can be used for operating the autothermal reforming of hydrocarbons inside the membrane reactor. In fact, as indicated by Tiemersma et al. (2006), the autothermal reforming of methane in a packed bed membrane reactor is quite difficult due to the hot spot at the reactor inlet which can melt down the membrane. This problem is completely circumvented in fluidized bed membrane reactors. In this case both autothermal reforming and hydrogen recovery can be performed in a single reactor.

According to Deshmukh et al. (2007) the main advantages of the MAFBR can be listed as follows:

- Negligible pressure drop, which allows using small particle sizes resulting in limited internal mass and heat transfer limitations (higher effectiveness factors)
- (Virtual) Isothermal conditions
- Flexibility in membrane and heat transfer surface area and arrangement of the membrane bundles
- Improved fluidization behavior as a result of:
 - Compartmentalization, i.e., reduced axial gas back-mixing.

Reduced average bubble size due to enhanced bubble breakage, resulting in improved bubble to emulsion mass transfer.

MAFBR for hydrogen production also circumvent the bed-to-wall mass transfer limitations affecting packed bed membrane reactors. It has been demonstrated that higher membrane fluxes (possible with nowadays membranes) will cause a significant increase of the concentration polarization in packed bed membrane reactors, even in membrane tubes with a diameter as small as 1 cm. By using the MAFBR, the membrane area required for a fixed hydrogen flux can be decreased by 50 % if compared with packed bed reactors (Gallucci et al. 2010a).

Even though Rahimpour and coworkers often used fluidized bed membrane reactor for distributive hydrogen feeding in methanol reactors (see Rahimpour and Lotfinejad 2008), most of the literature has focused on pure hydrogen

production through Pd-based membranes (see among others Adris et al. 1991; Prasad and Elnashaie 2002) and on autothermal reforming reactions (see a.o. Grace et al. 2001; Gallucci et al. 2010b).

Fluorescence

Carla A. M. Portugal
REQUIMTE-LAQV, Chemistry Department,
FCT-Universidade Nova de Lisboa, Campus da
Caparica, Caparica, Portugal

Fluorescence is a photoluminescence process which consists of the emission of photons along the de-excitation of molecular species from the excited state S_1 to the ground state S_0 . The loss

Fluorescence, Fig. 1 Perrin-Jablonski diagram schematizing the radiative (*bold lines*) and non-radiative (*dashed lines*) de-excitation processes

of energy by molecular species in the excited state may occur through radiative processes (i.e., with photon emission) or via nonradiative (i.e., without photon emission) de-excitation mechanisms, as schematized in Fig. 1.

Radiative de-excitation may occur via fluorescence or phosphorescence emission, whereas nonradiative de-excitation may occur through intersystem crossing or internal conversion mechanisms, which may be coupled to additional energy losses through vibrational relaxation to the lowest energy level. The former corresponds to electronic transitions between states with the same multiplicity whereas intersystem conversion implies an electronic transition between isoenergetic vibrational levels of different multiplicity (singlet to triplet states) (Valeur 2002). Electronic transitions from triplet state to the ground state are possible through radiative processes, such as phosphorescence or delayed fluorescence (upon returning to the excited singlet state).

Nonradiative de-excitation results from interactions between the excited species and other molecules in their close proximity (intermolecular processes) where energy loss is consequence of heat release due to molecular

collision, or electron, proton, and energy transfer. Also, it may involve excited state chemical reactions, leading to the formation of different molecular species (excimers or exciplexes). These intermolecular de-excitation mechanisms are responsible for fluorescence quenching, which is characterized by a fast electronic decay to the ground state and therefore it may compete with fluorescence, leading to a decrease of the fluorescence quantum yield, ϕ_F . Hence, ϕ_F expresses the ability of an excited molecule to decay to the ground state through fluorescence radiative process and can be determined by the equation

$$\phi_F = \frac{k_r}{k_r + k_{nr}}$$

where k_r and k_{nr} are the rate constants for radiative and nonradiative deactivation processes in the singlet state (Valeur 2002), respectively.

Fluorescence emission is highly sensitive to the intrinsic physicochemical characteristics of fluorophores and also to changes of its involving media. Indeed, steady-state fluorescence emission spectra acquired upon excitation with randomly oriented light allows at eliciting information about

the excited state molecular events occurring in equilibrium, based on changes in fluorescence intensity or maximum emission shifts (Portugal et al. 2006, 2007; Martinho et al. 2003). The former may be related with the variation of concentration of fluorophores present in the sample but also it may be ascribed to other molecular events such as fluorescence quenching, inner filter effects (e.g., light scattering or reabsorption of emitted light), and chemical reactions with the formation of different species. Instead, the presence of maximum emission shifts to lower (blue-shift) or higher (red-shift) wavelengths may evidence changes in the polarity in the vicinity of the fluorophores. Applied to intrinsic fluorophores of proteins, e.g., tryptophans, these spectral changes may reveal protein folding/unfolding processes (Portugal et al. 2006, 2007).

Fluorescence anisotropy corresponds to the fraction of polarized light emitted by a fluorophore upon excitation with polarized light, as expressed by the following equations (Valeur 2002):

$$r = \frac{\text{Polarized light}}{\text{Total light}} = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + 2I_{\perp}} = \frac{I_{VV} - I_{VH} \times G}{I_{VV} + 2 \times I_{VH} \times G}$$

$$G = \frac{I_{HV}}{I_{HH}}$$

where $I_{\parallel}$ represents the fraction of emitted parallel polarized light (I_{VV} and I_{HH}) and $I_{\perp}$ corresponds to the fraction of emitted perpendicular light (I_{VH} and I_{HV}).

Fluorescence anisotropy relates with the depolarization of light in the excited state due to the rotational freedom of the fluorophores. Therefore, fluorescence anisotropy may provide information about constraints imposed on the fluorophore by the system, molecule, or matrix where it is included in, through detection of changes of the fluorophore rotational ability (Lakowicz et al. 1983). Hence, the increase of fluorescence anisotropy may be ascribed to a decrease of fluorophore mobility. Recalling the example of tryptophan, changes of its mobility within the

protein chain may report protein folding/unfolding processes or changes of protein molecular flexibility, e.g., caused by protein adsorption/desorption mechanisms (Portugal et al. 2006, 2007).

The emission fluorescence spectra obtained in steady state correspond to the contribution of all the fluorescing species present in the system under analysis that are able to absorb energy at the selected excitation wavelength. The ability to discriminate the contribution of each fluorescing species depends largely on the system complexity, but it may be possible through determination of their individual fluorescence decay times (Beechem and Ludwig 1985). Fluorescence decay times may be elicited by fitting of adequate functions, e.g., sum of exponentials (where each parcel corresponds to the contribution of the single fluorescing species) described below (Beechem and Ludwig 1985; Valeur 2002).

$$I(\lambda, t) = \sum_i a_i e^{-t/\tau_i}$$

where $I(\lambda, t)$ is the variation of fluorescence emission along the time, a_i corresponds to the amplitude of the decay, t and τ_i are the measuring time and the fluorescence decay time, respectively.

Due to the high sensitivity of fluorescence emission and fluorescence decay times to changes of temperature, pH, ionic strength, and solvent properties (e.g., polarity, dielectric constant) and the presence of fluorescence quenchers in the surrounding media, some fluorophores have been efficiently used as fluorescence probes for monitoring of membrane-based processes. Fluorescence spectroscopy has been used toward the development of membrane materials less prone to fouling, through inspection of fluorophores adsorbed at the material surface (Gironès et al. 2006). Also, it can be used for monitoring the performance of membrane permeation processes (Crespo et al. 1999; Galinha et al. 2012).

Furthermore, it has been used to obtain a better comprehension about the impact of membrane processes on the structural and functional properties of biomolecules, e.g., proteins, using tryptophan as the structural probe. Using a fluorescence monitoring approach which combined the complementary information provided by steady-state fluorescence, fluorescence anisotropy, and time-resolved fluorescence it was demonstrated that under specific processing conditions (e.g., transmembrane pressure, membrane molecular weight cutoff, membrane chemistry) membrane permeation may induce irreversible changes of protein structure and function (Portugal et al. 2006).

Fluorescence Excitation-Emission Matrix (EEM)

Carla A. M. Portugal¹ and Claudia F. Galinha²

¹REQUIMTE-LAQV, Chemistry Department, FCT-Universidade Nova de Lisboa, Campus da Caparica, Caparica, Portugal

²REQUIMTE-CQFB, Chemistry Dept. Faculdade de Ciências e Tecnologia, FCT-Universidade Nova de Lisboa, Campus da Caparica, Caparica, Portugal

The fluorescence emission of molecular species depends on their intrinsic physicochemical characteristics and on their interactions with the surrounding media. Therefore, fluorescence emission is extremely sensitive to changes of the environmental conditions in the fluorophore's vicinity (e.g., pH, temperature, presence of fluorescence quenchers, solvent properties). Together, these factors define the period during which a fluorophore remains in the excited state, i.e., fluorescence lifetime, and the magnitude of each radiative and non-radiative de-excitation process component, through which the fluorophore decays to the ground state (the lowest energy level).

This dependency relation limits the use of fluorescence spectroscopy for quantitative purposes, but simultaneously it explains the potential of this technique to provide information about the system status using single or multiple fluorescence probes (fluorophores). The information about the molecular events occurring in the system may be obtained based on changes of the fluorescence emission of a single probe, through acquisition of the fluorescence signal at only one pair of excitation-emission wavelengths, generally corresponding to the specific maximum emission of the fluorophore. Alternatively, it may be elicited by selecting one of the fluorescence signal dimensions (excitation or emission wavelength) and scanning the other within the range of interest. Despite sensitive, this approach may hamper a complete system description since it reports only the media interactions with a single probe, discarding possible additional information captured by other fluorescence probes also present

Fluorescence Excitation-Emission Matrix (EEM), Fig. 1 Fluorescence excitation-emission matrices (EEMs) obtained at different locations of a MBR system

used for wastewater treatment: (a) feed wastewater, (b) activated sludge inside the bioreactor and (c) clarified permeate upon treatment

in the system, emitting in different spectral regions. Thus, a more thorough system characterization can be achieved by scanning simultaneously excitation and emission wavelengths in order to cover a larger spectral region and capture the information provided by each fluorophore present in the system. This 2D fluorescence monitoring approach results in tridimensional fluorescence maps having as coordinates the fluorescence emission intensity, excitation (λ_{Exc}) and emission (λ_{Em}) wavelengths, so-called excitation-emission matrices (EEM), as those illustrated in Fig. 1.

Therefore, EEMs may be regarded as system fingerprints encoding valuable information

concerning the presence of the fluorescence probes in the system (Marose et al. 1998) as well as their interactions with their involving media (Galinha et al. 2011). EEMs are thus a sum of constructive and destructive interferences of the media conditions with the probe intrinsic fluorescence. Constructive interferences are those that contribute to the increase of the fluorescence emission of a specific probe, thus facilitating its detection, such as those resulting from decrease of temperature or solvent polarity. Oppositely, destructive interferences are those that limit the detection of specific fluorescence response. Destructive interferences are quite common in

complex systems being caused by a large diversity of phenomena, such as (1) superimposition of emission spectra from different fluorescent solutes; (2) quenching effects, prompted by molecular species in close proximity to the probe, which interfere in the fluorophore de-excitation process reducing its fluorescence emission component; and (3) inner filter effects, including the re-absorbance of the emitted light by other solutes (e.g., when the absorption spectra of solutes superimpose, at least partially, the fluorophore emission spectra) and light scattering promoted, for instance, by the presence of suspended solids or turbidity.

Although it perturbs the direct measurement of the fluorophores (Galinha et al. 2011; Kobbero et al. 2008) and the access to convoluted data embedded in EEMs, interferences should be regarded as an additional rich source of information that can be disclosed by the use of adequate mathematic tools. Such approach has been applied for the characterization of different water streams (Galinha et al. 2011; Osburn et al. 2012) and for the monitoring of biological and wastewater treatment processes, namely, membrane bioreactors, MBRs (Fig. 1). Fluorescence monitoring has been used aiming to get a better understanding of membrane fouling mechanisms, in order to define adequate strategies, which may allow for the mitigation of fouling problems (Peiris et al. 2010). Mathematical approaches based on the use of multivariate statistical tools, combining principal component analysis (PCA or PARAFAC) and projection to latent structure (PLS) modeling (Galinha et al. 2012) or artificial neural networks (ANNs) (Wolf et al. 2001), allow for establishing relationships between EEMs and relevant process output variables, leading to an accurate prediction of some process performance descriptors (e.g., transmembrane pressure, chemical oxygen demand, total nitrogen, nitrites and nitrates, reaction rates).

2D fluorescence spectroscopy offers the possibility of simple, real-time, and non-invasive monitoring of biological or non-biological processes at different points of the system by using optical fibers. Moreover, it allows accurate prediction of process performance parameters and the potential

anticipation of process problems without the need of the traditional time-consuming analytical methodologies.

Fluxes and Driving Forces in Membrane Separation Processes

Xianhui Li and Jianxin Li

State Key Laboratory of Separation Membranes and Membrane Processes, School of Materials Science and Engineering, Tianjin Polytechnic University, Tianjin, China

The transport rate of a component through a membrane is determined by the permeability of the membrane and by the driving force. Generally, the flux through a membrane can be described by

$$J = -P \frac{dX}{dz} \quad (1)$$

where J is a flux, P is a phenomenological coefficient expressing the permeability of the membrane, and $\frac{dX}{dz}$ is the driving force. The flux through the membrane can be defined as volume flux (J_v) expressed in volume per time ($\text{m}^3 \cdot \text{s}^{-1}$), mass flux (J_m) expressed in mass per time ($\text{kg} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$), molar flux (J_n) expressed in mole per time ($\text{mol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$), electrical flux (J_e) expressed in Faraday per time ($\text{A} \cdot \text{m}^{-2}$), and heat flux (J_q) expressed in heat per time ($\text{J} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$).

Fluxes and Driving Forces in Membrane Separation Processes,

Fig. 1 The schematic diagram of mass transport through a membrane

The driving forces in membrane processes are gradients in the chemical potential, the electrical potential, and the hydrostatic pressure, which could result in a diffusion of individual molecules, a migration of ions, and a convection of mass, respectively. The function of the membrane is illustrated in Fig. 1. The transport of the component A from phase 1 through a membrane into the phase 2 is due to the driving force as shown in Fig. 1.

According to the driving forces, the membrane processes can be classified into the pressure-driven processes (reverse osmosis, ultra- and microfiltration, and gas separation), the concentration gradient-driven processes (dialysis), partial pressure-driven processes (pervaporation), and electrical potential-driven processes (electrolysis and electrodialysis). The main driving forces in the different membrane processes are illustrated in Table 1. It can be seen in Table 1 that the hydrostatic pressure differences are used in micro- and ultrafiltration, as well as in reverse osmosis and gas separation as driving force for the mass transport through the membrane. The mode of transport in micro- and ultrafiltration is convection. However, in reverse osmosis and gas separation, the mode of transport is diffusion, and the actual driving forces are chemical potential and fugacity gradients. The mode of transport in dialysis is diffusion with concentration or activity

Fluxes and Driving Forces in Membrane Separation Processes, Table 1 The driving forces applied in the various membrane separation processes (Strathmann 2001)

Process	Driving force	Transport mode
Microfiltration	Hydrostatic pressure (Δp)	Convection
Ultrafiltration	Hydrostatic pressure (Δp)	Convection
Reverse osmosis	Hydrostatic pressure (Δp)	Diffusion
	Chemical potential ($\Delta \mu_i$)	
Dialysis	Concentration (ΔC)	Diffusion
	Activity (Δa)	
Gas separation	Hydrostatic pressure (Δp)	Diffusion
	Fugacity (Δf_i)	
Pervaporation	Partial pressure (Δp_i)	Diffusion
	Fugacity (Δf_i)	
Electrodialysis	Electrical potential ($\Delta \phi$)	Migration

gradients as driving forces. And an electrical potential gradient in electrodialysis is used to achieve a migration of charged ions across the membrane.

In order to describe the transport processes through membranes, a number of equations which are related to the fluxes of various components to the corresponding driving forces in the form of linear relations are developed as follows:

Fourier's law

$$J_q = -\alpha \frac{dT}{dz} \quad (2)$$

Fick's law

$$J_n = -D \frac{dC}{dz} \quad (3)$$

Darcy's law

$$J_v = -L_p \frac{dp}{dz} \quad (4)$$

Ohm's law

$$J_e = \kappa \frac{d\phi}{dz} \quad (5)$$

Herein T is the temperature, C is the concentration, p is the pressure, ϕ is the electrical potential, α is the heat transfer coefficient, D is the diffusion

coefficient, L_p is the hydrodynamic permeability, and κ is the electric conductivity.

Fourier's law describes the relation between heat transport and a temperature gradient. Fick's law describes the relation between the flux of individual components and a concentration gradient. Ohm's law describes the relation between an electrical current and an electrical potential gradient, and Darcy's law describes the relation between a volume flux and a hydrostatic pressure difference. These two factors should be interlinked: a high driving force yields the high flux and a high rate of foulants deposition on the membrane surface. Therefore, driving forces and fluxes are interdependent in membrane processes.

Food Packaging

► [Food Packaging, Membranes for](#)

Food Packaging, Membranes for

Alberto Figoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

[Food packaging; Membrane operations](#)

Food packaging is often defined as a heterogeneous group of boxes, envelops, papers, and coatings that are employed in order to increase foodstuffs shelf life (European Council 1994). This means that any food packaging system aims to avoid/slow down bacterial/fungal

Food Packaging, Membranes for,

Fig. 1 Application of membrane in traditional food packaging, revised from ref. (Figoli et al. 2010)

contamination and deterioration and, at the same time, to ensure the maintenance of properties as firmness, color, and flavor as long as possible.

Nowadays, beside the traditional concept of packaging as impenetrable barrier, novel systems are required, such as *modified atmosphere packaging* (MAP) and *active packaging* (AP). Polymeric membranes, thanks to their unique properties of permselectivity and ability to sustain controlled delivery, can be successfully used for food packaging; indeed, their properties can be exploited for such innovative packaging systems (Figoli et al. 2010), as also shown in Fig. 1. Furthermore, the expertise of membranologists could help to produce food packaging systems from biodegradable nonpolluting sources. In particular, the properties of films produced from *biopolymers* can be improved by well-developed techniques as blending, use of plasticizers, and loading with nanoparticles.

MAP is frequently used in the case of fresh, or minimally processed, respiring, products, like vegetables and fruits. MAP aims at maintaining an optimum gas balance in the package headspace. In particular, a selected ratio between carbon dioxide and oxygen is often required in order to allow living vegetal tissues respiration and survival, at the same time preventing aging and deterioration. The respiratory quotient (RQ) (Cameron et al. 1995) is defined as the optimum balance between O_2 and CO_2 that should be maintained within the package; this value is peculiar of each fruit or vegetable specimen. MAP requires films having specific permselectivity to gases, such as carbon dioxide and oxygen, rather than impenetrable materials. In this case, gas separation membranes can be particularly useful, while membrane materials can be selected, in each case, on the basis of their permselectivity to

oxygen and carbon dioxide. By varying the ratio between polymer and additive concentrations, dense membranes in modified polyether ether ketone (PEEK-WC) and poly- α -pinene (P α P) were reported to match the values required by different products, as apple, Brussels sprouts, carrot, green pepper, and turnip (Torchia et al. 2004).

A wide range of CO_2/O_2 permselectivity values can be obtained by using packaging structures based on biopolymers. These are defined as biodegradable materials that can be decomposed by microorganisms and enzymatic degradation. Starch, cellulose, chitosan, polycaprolactone (PCL), and polylactic acid (PLA) are some examples of biopolymers suitable for food packaging (Mensitieri et al. 2011). In literature, several studies already demonstrated that biopolymers can compete with oil-derived plastics for packaging of different fruit and vegetable species (see for instance ref. Conte et al. 2009; Kantola and Helen 2001; Muratore et al. 2005; Srinivasa et al. 2002). However, hydrophilicity and poor mechanical properties are the main drawbacks for use of biopolymers as food packaging systems. Several strategies, already developed in the field of membrane science and technology, can be useful to improve properties and processability of biopolymers for food packaging, such as use of chemical additives (plasticizers, antioxidants, stabilizers) (Torchia et al. 2004; Abdorreza et al. 2011), blending (Torchia et al. 2004; John et al. 1998; Sarazin et al. 2008), chemical cross-linking (González et al. 2011; Yu et al. 2011), or use of nanofillers (Belbekhouche et al. 2011; Chivrac et al. 2009; Famá et al. 2011; Hu et al. 2011; Li et al. 2011).

Active releasing packaging systems are used to control the delivery of specific substances to the

packed product. Membranes loaded with specific substances, coated on the surface, or entrapped in the polymeric matrix can be useful in this case, similar to what already developed in the medical field (Baker 2002). Membranes can be used to sustain the controlled delivery of antimicrobial substances, such as allyl isothiocyanate (AITC) (Lee et al. 2008) or oxalic acid (Figoli et al. 2004). Active release can be also combined with use of biopolymers. Films based on starch, corn zein, and PLA can be used for delivery of lysozyme, nisin, and natural antimicrobial compounds (Torchia et al. 2004); literature reports several other interesting examples of biopolymer-based films as active packaging systems (Atarés et al. 2011; Chana-Thaworn et al. 2011; Gemili et al. 2009; Sánchez-González et al. 2011). Microencapsulation is another strategy for controlled delivery. It has been shown that it can be used coupled to traditional packaging materials or biopolymers for active packaging systems releasing natural antimicrobials (Guarda et al. 2011) or aroma compounds (Marcuzzo et al. 2010).

Food Processing by Membrane Operations

Angela C. Macedo¹ and F. Xavier Malcata²

¹LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

²DEQ – Department of Chemical Engineering and LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

Food processing consists of transformation of raw ingredients into food, or food itself into other forms. Food processing typically starts with clean, harvested crops or butchered animal products and uses them to produce safe and attractive products – along the food chain, down to the consumer at home (Marsh and Angold 2004). Various unit operations are part of the current practice, which rely on either thermal processing or mechanical work: the former are less appropriate to heat-labile items and are also characterized by poor thermodynamic efficiency. Mechanical work is, to advantage, applied in membrane-based processes: they take advantage of a physical barrier (i.e., a porous membrane or filter) to separate particles

from a fluid based on their size and shape and resort to high pressure and tailor-made membranes with specific pore sizes. The pore size distribution allows indeed different possibilities in terms of separation to be attained – via microfiltration, ultrafiltration, nanofiltration, and reverse osmosis (sorted by decreasing pore size) (Drioli et al. 2011).

Membrane processing has met with industrial success in clarification and concentration of liquid foods because it operates at room temperature, entails low energy consumption, and is highly preformant with regard to a wide range of contaminants – besides scaling up easily (Sant’Anna et al. 2012); it may also increase yield, and its high selectivity can be taken advantage to improve control (Drioli et al. 2011). Membranes are able to remove sediments, microorganisms, and large-sized compounds; they offer indeed an efficient way to gain superior quality and safety without disturbing the basic sensory profile of a food product. As major disadvantages, one should outline high hydraulic pressure drops, limited maximum attainable concentration, and concentration polarization – especially in media with high loads of organic compounds (Petrotos et al. 2010).

Microfiltration separates suspended particles, typically from 0.1 to 10 μm (thus including bacteria); for sterilization purposes, 0.4–0.6 μm membranes in dead-end and cross-flow filtration modes are recommended. Permeate fluxes of the order of 100,000 $\text{L}\cdot\text{m}^{-2}\cdot\text{h}^{-1}$ are typically observed when processing (clean) water; liquid foods usually reduce such a permeate flux to 100–200 $\text{L}\cdot\text{m}^{-2}\cdot\text{h}^{-1}$, owing primarily to viscosity, fouling, and concentration polarization (Accomazzo et al. 1988).

Ultrafiltration resorts to membranes with pore sizes in the range of 0.1–0.001 μm ; it is typically intended for removal of high molecular weight substances, colloidal materials, and polymeric molecules of organic or inorganic nature. Ultrafiltration is a cross-flow separation process – i.e., the liquid feed flows tangentially along the membrane surface with a pressure drop across it, causing part of that stream to percolate the membrane (thus producing a permeate). The type and amount of species left in the remaining stream (retentate) depend on the characteristics of the membrane

and the operating conditions, as well as the composition of the original feed. Optimum design and operation should take into account the flow velocity, the pressure drop, the power consumption, the rate of membrane fouling, and the module cost. Since only high molecular weight species are removed, the differential in osmotic pressure across an ultrafiltration membrane is usually negligible (Accomazzo et al. 1988).

Nanofiltration is a ► [cross-flow filtration](#) technology, usually listed between ultrafiltration and reverse osmosis; the nominal pore size of the membrane is typically ca. 1 nm, but the ► [molecular weight cutoff](#) – which is typically less than 1,000 Da, rather than the nominal pore size – is to be used for a more meaningful characterization. Transmembrane pressures can go up to 3 MPa, which require powerful pumping equipment; furthermore, nanofilter membranes are quite susceptible to scaling and fouling, so such modifiers as antiscalants are often required.

Finally, reverse osmosis goes one step further in filtration and allows separation of small dissolved molecules in the Angstrom range; this includes salts, sugars, and organic acids. The only driving force for this process is the osmotic pressure difference between the solutions lying on the two sides of the permeable membrane. The cross-flow configuration allows the membranes to self-clean continually; further advantages encompass relatively low hydraulic pressure and easy scale-up (Sant'Anna et al. 2012).

Membrane contactors represent another approach to membrane operations in food processing – where separation does not rely specifically on the membrane acting as selective barrier, but is instead based on phase equilibria. Hence, mass transfer between phases is promoted without dispersing one phase into the other, and such disadvantages as flooding at high flow rates, unloading at low flow rates, requirement for emulsified state and density differences, and high interfacial area are dramatically alleviated. In principle, all traditional stripping, scrubbing, absorption, evaporation, distillation, crystallization, emulsification and liquid-liquid extraction, as well as enzymatic catalysis can be carried out

following this configuration. This type of contactor technology has found applications in purification of water, wine fermentation, protein extraction, and beverage carbonation (Stanojević et al. 2003).

Formulation by Membrane Emulsification

Goran T. Vladislavljević and Richard G. Holdich
Department of Chemical Engineering,
Loughborough University, Loughborough,
Leicestershire, UK

Membrane emulsification (ME) is a process of forming emulsion by passing a pure dispersed phase or pre-emulsion through a microporous membrane (Fig. 1). The most commonly used membranes for ME are Shirasu porous glass (SPG) membrane and microsieve membranes. In direct ME, fine droplets are produced at the membrane/continuous phase interface by injecting a

Formulation by Membrane Emulsification, Fig. 1 Two different approaches used to obtain fine droplets of oil-in-water emulsion in membrane emulsification

(ME): a “bottom-up” approach (direct ME); b “Top-down” approach (premix ME)

pure liquid (the dispersed phase) through the membrane into a second immiscible liquid (the continuous phase) (Nakashima et al. 1991). The dispersed phase should not wet the membrane wall, i.e., hydrophobic and hydrophilic membranes are used to produce water-in-oil and oil-in-water emulsions, respectively. At low trans-membrane fluxes, uniform droplets can be formed without applying any shear on the membrane surface, solely by the action of interfacial tension (Kukizaki 2009). In order to achieve commercially significant throughputs in ME, the shear stress is applied at the continuous phase/membrane interface, usually by cross flow or stirring (Fig. 2a–d). Cross-flow systems are easy to scale up and can offer a continuous operation and constant shear stress along the membrane surface. Stirring systems are operated batchwise and do not provide constant shear stress on the membrane surface, but are easier to operate because a closed loop recirculation of the continuous phase stream is not needed and a batch size can be very low, just 10 mL or even less.

The shear stress can also be generated by a dynamic membrane (Fig. 1e) or pulsed flow (Fig. 1f), in which case the droplet detachment from the membrane surface is facilitated by

rotating (Vladislavjević and Williams 2006) or vibrating (Holdich et al. 2010) the membrane within the otherwise static continuous phase or providing periodic flow pulsations in the continuous phase (Holdich et al. 2013). In the dynamic and pulsed flow membrane systems, the shear stress on the membrane surface is decoupled from the cross-flow velocity, and consequently, sufficiently high shear stress can be achieved at any cross-flow velocity, and emulsions with high dispersed phase concentrations can be produced in a single pass through the module.

In the dripping regime, the droplet size is determined by a balance between the shear force and the capillary force. The size of the droplets produced is mainly affected by the microstructure of the membrane (the pore size distribution, pore shape, and pore spacing), transmembrane flux, surface shear stress, physical properties of the continuous and dispersed phase, and emulsion formulation. Surfactant molecules must not adsorb to the membrane surface, and thus, cationic surfactants must not be used in association with negatively charged membrane (such as SPG membrane and oxidized silicon microsieves) (Nakashima et al. 1993). The transmembrane pressure should not exceed ten times the capillary

Formulation by Membrane Emulsification, Fig. 2 Different ME systems used to control shear stress on membrane surface (Vladisavljević and Williams 2005)

pressure and the shear stress on the membrane surface is usually in the range from 2 to 10 Pa (Vladisavljević et al. 2004). The droplet size is typically two to ten times higher than the pore size and decreases with increasing the shear stress on the membrane surface.

Forward Osmosis (FO)

Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

In literature, osmotic pressure-driven membrane processes are known as direct osmosis (DO) or forward osmosis (FO). FO dating back to the early 1960s is a membrane contactor process that utilizes osmotic pressure difference ($\Delta\pi$) across the membrane for water transport through a semipermeable membrane (Cartinella et al. 2006; Cath et al. 2006) than a hydraulic pressure as in RO. The osmotic pressure difference across the membrane arises from the use of concentrated solution called draw solution (DS) on the permeate side of the membrane (Fig. 3a). Apparently FO may be a viable and sustainable alternative to thermal-driven (membrane distillation) and pressure-driven (reverse osmosis) concentrating methods, which are highly energy intensive, hence very expensive. In the presence of natural sources of concentrated DS, e.g., seawater, FO can be very attractive due to its significantly lower energy demand for pumping (Tang et al. 2010). The equation below is generally used to describe water transport in FO:

$$J_w = A(\sigma\Delta\pi - \Delta P) \quad (1)$$

where J_w is the water flux, A the water permeability constant of the membrane, σ the reflection coefficient, and ΔP is the applied pressure. For FO, ΔP is zero.

Currently many researchers are focusing on the use of FO for different applications, and remarkable progresses are observed in optimizing the process through testing different DS, configurations, and development of model equations that could best explain the phenomena.

Hence, FO is reemerging as low-energy demanding membrane operation ($<30 \text{ kWh/m}^3$) (Beaudry et al. 1999) for dehydration of aqueous solution

(Klaysom et al. 2013), seawater desalination (McCutcheon et al. 2005), wastewater treatment and concentration of diluted streams (Holloway et al. 2007), food processing (Petrotos et al. 1998), removal of trace organic matter (Cartinella et al. 2006), and for use in membrane bioreactor (Zhang et al. 2012). As shown in Fig. 1, there is an exponential rise in the number of FO-related publications in the last 5 years. Similarly, the number of patents released from 2009 to 2014 is significantly high (Fig. 2), providing a pertinent prospect to its application in various fields.

The following are summaries of the range of potential advantages of FO process:

- Requires low/no hydraulic pressure since it is an osmotically driven process.
- Low energy consumption, thereby lowering costs, if suitable draw solutes and their regeneration methods can be economically and technically developed.
- Energy can be harvested from the mixing of freshwater and saline water by pressure-retarded FO (PRO).
- Membrane fouling in FO is relatively low and more reversible and can be minimized by optimizing the hydrodynamics.
- Numerous contaminants can be effectively rejected by the FO process.
- Has the potential to help achieve high water recovery, which reduces the volume of desalination brine, a major environmental concern for current desalination.
- In the food and pharmaceutical processing, FO can maintain color, taste, aroma, and nutrition of the feed.
- In the medical applications, FO can help in the controlled release of drugs with low oral bio-availability in a controlled manner by osmotic pumps.

FO Membranes, Membrane Configurations, and Modeling Membrane Transport

Except for a few authors such as McCutcheon et al. (2005) which used a thin-film composite

polyamide membrane, most publications are based on cellulose or cellulose derivate (cellulose acetate) membranes mainly from Hydration Technology Inc. In addition, in most cases reverse osmosis (RO) was used to reconcentrate the DS which gets diluted in the course of FO.

Of the different membrane modules, spiral wound modules are one of the most common

packing configurations in the membrane industry. However, it cannot be used in its current design for FO because a liquid stream cannot be forced to flow on the support side (inside the envelope) (Cath et al. 2006). Hence, for a continuous FO operation, flat-sheet membrane and specially designed spiral wound membrane are used. Although applied in limited number, tubular

membranes are also very suitable for continuous FO processing since they are self-supported, can be fabricated easily, and allow free flow of liquid on both sides of the membrane.

There are a number of papers discussing the transport phenomena in FO process in particular related to solution physicochemical properties, concentration polarization, and membrane fouling. For detailed reading, the reader is referred to Tang et al. (2010), McCutcheon and Elimelech (2006), Tan and Ng (2008), and Zhao and Zou (2011).

Draw Solutions

In FO process, a concentrated solution on the permeate side of the membrane is the source of the osmotic driving force. In literature, various names are given to this solution including: draw solution, osmotic agent, osmotic media, driving solution, osmotic engine, sample solution, or brine (Cath et al. 2006). The main criterion for selecting the type of draw solution (DS) is its potential to create higher chemical potential than the feed solution.

The DS and related osmotic pressures in the FO process are important factors influencing overall process performance. Many researchers used salt solution as DS (Cartinella et al. 2006; Cornelissen et al. 2008; Yong et al. 2012), while in some cases sugars or ammonia–carbon dioxide (McCutcheon et al. 2005) solutions were used. According to Lutchmiah et al. (2014), based on publication from 2005 to 2013, 40 % of the cases utilized NaCl as DS. This is mainly attributed by its high solubility (Cath et al. 2006), low cost (Achilli et al. 2010), and relatively high osmotic potential. The same author indicated that 12 % used MgCl_2 , 8 % sugars, 10 % sulfates, and other 7 % used magnetic nanoparticles, real wastewater, carbonates, etc. In addition to these, seawater has frequently been used as a DS (Cath et al. 2010). However, its use was mostly affected by abundant presence of particles and microorganisms which may foul the subsequent system used to reconcentrate the DS (in closed-loop systems) or cause fouling/biofouling in the FO unit, hampering performance.

Concentration Polarization and Membrane Fouling

Unlike pressure-driven membrane process, in FO there are both dilutive and concentrative polarization effects that result in a lower-than-expected water flux. Furthermore, the concentration polarization could be either external which occurs near the surface of the active layer and the porous support layer or internal which occurs inside the substructure of porous support layer. As a result, the process is always accompanied by great reduction from the bulk osmotic pressure ($\Delta\pi_{\text{bulk}}$) to the effective osmotic pressure ($\Delta\pi_{\text{effective}}$) as shown in Fig. 3b.

External Concentration Polarization

When the process is in FO mode of operation, i.e., feed solution facing the active side of the membrane, there is accumulation of solute that is rejected by the membrane. This will result in the phenomena of concentrative external concentration polarization (ECP). At the same time, the DS in contact with the permeate side of the membrane gets diluted by the permeating water at the permeate–membrane interface resulting in dilutive external concentration polarization (ECP). Due to these phenomena, the effective osmotic driving force near the membrane is significantly lower than the bulk (apparent) osmotic pressure (Cath et al. 2006).

Interestingly, several studies have shown that fouling induced by ECP in FO in most part is reversible due to low foulant compaction as a result of the negligible hydraulic pressure gradient. Therefore, FO holds a great potential to treat wastewater (Lutchmiah et al. 2014), including wastewater with high fouling propensity (Cicci et al. 2013; Karaouzas et al. 2011). The main strategy utilized to reduce the effect of ECP is increased turbulence or cross flow velocity. Moreover, recovering FO membrane performance was possible using simple osmotic back flush, after it is fouled. For example, an intermittent osmotic back flush has given the possibility to use a single FO membrane over several cycles bringing the total membrane use to 172 h, during the treatment of vegetation wastewater (Gebreyohannes

Forward Osmosis (FO), Fig. 3 Water flows in FO system where (a) water diffuses to the more saline side of the membrane due to osmotic driving force under approximately zero hydraulic pressure and (b) the course

of bulk osmotic driving force reduction to effective osmotic driving force due to concentration polarization phenomena

et al. 2015). This is an important savings in lifetime, compared to the complete performance loss observed in various pressure-driven membrane operations. The FO fouling is generally more pronounced when the porous support layer is facing feed solution, since this orientation is prone to sever internal pore clogging.

Internal Concentration Polarization

The asymmetric FO membrane consists of a dense active layer and a porous support layer, which adds a more complex situation of concentration polarization in FO. In FO applications, where the active layer of the membrane faces the feed solution and the porous support layer faces the DS, there is also dilutive internal concentration polarization (ICP) within the porous substructure. This phenomenon happens when water diffuses through the active layer; the DS within the porous substructure becomes diluted, hence dramatically reduced effective osmotic driving force. Unlike the external concentration polarization, playing with the hydrodynamic condition will not alleviate the problem of ICP. Thus, an engineered solution for reduced internal concentration polarization is optimization of the thickness,

porosity, and tortuosity of the porous substructure (Cornelissen et al. 2008). It is worth noting that compared to ECP, ICP has a more prominent effect in significantly reducing the effective driving force across the dense layer from the bulk osmotic difference.

Promising Application Areas

FO has been studied for a number of applications including commercial applications, in the water and wastewater treatment (e.g., extraction bags) and in the pharmaceutical industry (e.g., osmotic pumps), seawater/brackish water desalination, food processing, drug delivery, and electric power generation. For instance, FO was used to concentrate an oily wastewater from olive millings after removing courser particles in two different configurations. In the first case the pre-filtered wastewater directly fed to the FO process, while in another case permeate of biocatalytic membrane reactor was used as feed. In both cases, FO helped to reduce up to 70 % of the initial volume while completely rejecting all pollutants in the course of reclaiming purified water and pharmacologically important compounds. As a

Forward Osmosis (FO), Table 1 Examples of industrial plants that employed FO process

F

result it reduced the size of downstream process required to further fractionation and concentration of the recovered pharmaceutically interesting compounds.

Table 1 gives summary of industrial practices on the use of FO process in various fields. It is worth noting that in most wastewater treatment applications, FO is used as a high-level pretreatment step before an ultimate purification step. An exception for this is a hydration bag, which serves as a final treatment step to produce potable water from wastewater.

Concluding Remark

Regardless of the limited presence of robust membranes and membrane modules for FO, fundamental research on FO and the development of new applications of FO are growing fast. However, the following points need to be addressed to have a reliable commercial success:

- Development of new membranes in both flat-sheet and hollow fiber configurations: The development needs to orient in the production of membrane and modules with high water permeability, high solute rejection, limited ICP, high chemical and mechanical stability,

and high-density packing methods for well-performing flat-sheet FO membranes.

- Development of DS: Most desirable DS needs to induce high osmotic pressure, requires low energy for reconcentration, and must be easily separable from the product freshwater and nonreactive with low or no toxicity.

Introduction

The forward osmosis membrane bioreactor (FOMBR) is a new type of membrane bioreactor (MBR) technology, which combines two basic processes – biological degradation of organic wastes and membrane separation using forward osmosis (FO) – into a single process for various wastewater treatments (Zhang et al. 2012). Specifically, in a FOMBR, suspended solids and microorganisms responsible for biodegradation are separated from the treated water using a FO membrane module, where water is extracted from the mixed liquor through a semipermeable FO membrane to a high osmotic pressure draw solution (Achilli et al. 2009). The output from the FOMBR is a mixture of treated water permeate and the draw solution. A posttreatment step, such as reverse osmosis (RO) or membrane distillation (MD), can be used to produce purified water and to regenerate the draw solution.

Compared with conventional MBRs, where pressure-driven membrane filtration units are used, the FOMBR enjoys important advantages including potentially lower energy requirement and better water quality, because the separation does not entail the use of hydraulic pressure, and the salt-rejecting dense membrane is an absolute barrier to suspended solids and also retains organic species. In addition, the use of the dense membrane allows retention of recalcitrant organics which are eventually degraded, as

Forward Osmosis Membrane Reactor,

Fig. 1 Submerged FOMBR

Forward Osmosis Membrane Reactor, Fig. 2 Side-stream FOMBR

organic retention time (ORT) can be significantly longer than the hydraulic retention time (HRT). A greatly enhanced removal of micropollutants is also expected, which is a distinct advantage if the effluent is considered for reclamation and reuse.

Configurations of FOMBR

Similar to conventional MBRs, the FOMBR can be operated under two configurations. One is the submerged FOMBR as shown schematically in Fig. 1 and the other is side-stream FOMBR, as illustrated in Fig. 2 (Yap et al. 2012). In both

configurations, the driving force for water transfer is the osmotic pressure gradient across a salt-rejecting dense membrane. When water is extracted into the draw solution, the diluted draw solution is, subsequently, sent to a regeneration device (e.g., RO or MD) to recover the purified water. The commonly used FO membrane has an RO-like or nanofiltration (NF)-like selective layer that has high rejection toward organic/inorganic compounds in the wastewater including ions. Normally two-phase flow around fiber bundles (for a hollow fiber module) or between vertical flat plates (for a flat sheet membrane module) by air scouring is used to control membrane fouling and module blocking.

Major Challenges for Large-Scale Applications

There are three major technical challenges that impede large-scale applications of FOMBRs. Firstly, an appropriate membrane is essential to improve the performance of the FOMBR. Commonly used FO membranes consist of a dense-selective layer supported by a porous substrate. The membrane should exhibit high water flux and high salt rejection and be able to limit feed-side fouling and internal concentration polarization (ICP), which is a unique phenomenon in the forward osmosis process, causing the reduction of the effective osmotic driving force. The strategy to overcome the problem is to design the support layer of the FO membrane as thin and porous as possible to reduce mass transfer resistance, and thus, less severe ICP is expected (Wang et al. 2010). Fouling is a common issue in a conventional MBR as the wastewater is a complex system containing microorganisms, extracellular polymeric substances (EPS), and soluble macro-/microorganics and inorganics. FOMBR, on the other hand, has an additional potential scaling issue caused by inorganic salts due to solute accumulation (Zhang et al. 2012).

Secondly, the bioprocess must be optimized to handle accumulated recalcitrant organics, nutrients, and elevated salt concentrations, as the FO membrane possesses a dense-selective layer with high retentions to the organic species and salts. The accumulation of organic matters improves the biological degradation which may enhance the removal of micropollutants. The salt accumulation, however, (i) could have adverse effects on biological treatment and cause microbial inhibition (Zhang et al. 2012; Nawaz et al. 2013); (ii) reduces the osmotic driving force available, resulting in the reduction of water flux; and (iii) increases the concentration of sparingly soluble salts, and spontaneous chemical precipitation may occur when the saturation limits are exceeded, leading to scaling on the FO membranes.

The third challenge relates to draw solute selection and regeneration. A proper draw solution is necessary to provide high osmotic pressure and low salt back diffusion (Cath et al. 2006). When the salts from the draw solution diffuse to

the feed tank, the driving force will be reduced, leading to flux decline and toxic effects on the microbial community. In addition, the draw solution must be able to be regenerated easily and economically for reuse (Cornelissen et al. 2008).

Fossil Fuels Processing by Membrane Operations

May-Britt Hägg

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, Norway

Control of anthropogenic emissions of greenhouse gases (GHG) is one of the most challenging environmental issues related to global climate change. The larger part of emissions are coming from fossil fuels. The Energy Information Administration (EIA) 2010 predicted a 49 % increase of

Fossil Fuels Processing by Membrane Operations, Table 1 Overview of global stationary CO₂ sources larger than 0.1 million tons (Mt) of CO₂/year

Process		Number of sources	Emissions (Mt CO ₂ /year)
Fossil fuels	Power	4,492	10,539
	Iron and steel industry	269	646
	Cement production	1,175	932

Total		7,887	13,468

(IPCC special report on CCS, working group III)

energy demands from 2007 to 2035 following more and more countries becoming industrialized. The International Energy Outlook 2010 reference case reported that world energy-related carbon dioxide (CO₂) emissions would increase from 29.7 billion metric tons in 2007 to 33.8 billion metric tons in 2020 and 42.4 billion metric tons in 2035 (IEO 2010). The emissions of the greenhouse gas CO₂ is produced in a variety of ways as shown in Table 1 (Hay and Firman 2002). Among them, fossil fuel power plants are responsible for roughly 40 % of total CO₂ emissions, and coal-fired power plants being the main contributor. Changing from fossil energy to alternative renewable energy would be ideal; however, we will still be dependent on fossil fuels for many years ahead both due to limitations of technology development and also increased growth. Hence, carbon capture and sequestration (CCS) is seen as an efficient way to mitigate the emission of CO₂ in order to fight against global warming. The key motivation for CCS is that we may continue to use fossil fuels without causing significant CO₂ emissions. Clearly coal-fired power plants need to be firstly tackled, especially by retrofitting capture to existing plants. Different techniques such as chemical and physical absorption, physical

adsorption, cryogenics, and membrane separation may be used for CO₂ capture. Membranes are already an alternative and competitive technology for other selected gas separation processes such as natural gas sweetening, biogas upgrading, and hydrogen production during the last two or three decades. Alternative ways of using membranes for fossil fuel processing at power plants are illustrated in Fig. 1. Additionally, membranes are also being used for CO₂ removal from natural gas and upgrading of biogas.

Postcombustion: The membrane is then typically retrofitted to the plant as an end-of-pipe solution, and the main gas components are CO₂ and N₂. For a coal-fired power plant the content of CO₂ will be 10–15 %, while for a natural gas plant the CO₂ content may be as low as ~5 % unless there is an integrated solution. The flue gas will at this point have a temperature of around 70 °C and is at atmospheric pressure. These conditions are in general not very favorable for membrane separation as there is hardly any driving force, and much energy must be used in order to create sufficient partial pressure difference over the membrane. The recommended membrane solution in this case will be to use a membrane with very high flux and selectivity which can be achieved with a facilitated transport membrane having a fixed or mobile carrier to enhance the transport (Kim et al. 2004), or to use an innovative two-stage process solution where air is being used as sweep on the second stage and fed to the burner (Merkel et al. 2010). In both cases, energy demand is minimized by using only a fan on the feed side and pulling vacuum on the permeate side. The membrane material will be polymeric. Impurities in the flue gas stream (SO₂, NO_x, particles) may be a challenge for the membrane material.

Precombustion: When used in precombustion the membrane will be an integrated solution with the gas turbine and CO₂ may thus be removed at higher pressure. After the shift reaction H₂ and CO₂ will be in a mixture, with close to 40 mol% CO₂. The pressure will be in the range of 25–30 bar, and temperature around 300–350 °C unless there has been a sulfur removal unit up front of the membrane. The high temperature,

Fossil Fuels Processing by Membrane Operations,

Fig. 1 Alternative membrane processing at a power plant

pressure, and concentration are very favorable for Palladium membranes which can achieve extremely efficient separation of the two main components, allowing hydrogen to permeate (Jordal et al. 2004). An advantage is also that CO₂ is captured at high pressure, and less energy

will be needed for sequestration. The main challenge for this membrane solution is the module construction at this high temperature and also potential poisoning of the membrane.

Oxyfuel combustion: This solution is very elegant, using a membrane to separate out pure

oxygen. The air separating membrane is, however, still not fully developed. These membranes are suitable for advanced power generation requiring pure oxygen for combustion or gasification and are based on zirconia and perovskite where oxygen is transported through the material as O_2^- . The materials are stable at very high temperatures ($>500^\circ C$) but again module design is very challenging at these high operating temperatures.

[Fouling in membranes](#); [Membrane fouling](#)

An intrinsic phenomenon of all membrane separation processes is the decline of the flux through the membrane as a function of time, due to concentration polarization effects and the formation of cake or gel layers by feed solution constituents retained by the membrane. Equally devastating

for the performance of a process is membrane fouling. Membrane fouling is a general term. It may be the result of concentration polarization; it may also be the consequence of adsorption of feed solution constituents at the membrane surface and especially in microfiltration also within the membrane structure. The control of concentration polarization and membrane fouling is a major engineering aspect in the design of membrane separation processes and equipment (Brian 1966; Blatt et al. 1970; Jonsson and Boesen 1984; Bian et al. 2000; Hoek and Elimelech 2003; Cornelissen et al. 2004).

Concentration polarization effects will occur in all membrane separation processes. Its consequences, however, are especially severe in pressure-driven membrane processes. When in a mass separation procedure a molecular mixture is brought to a membrane surface, some components will permeate the membrane under a given driving force, while others are retained. This leads to an accumulation of retained material and to a depletion of the permeating components in the boundary layers adjacent to the membrane surface. This phenomenon is referred to as concentration polarization. The causes and consequences of concentration polarization may be rather different in different membrane processes. Often the adverse effects of concentration polarization are intensified by an adsorption of certain feed mixture constituents at the membrane surface. This phenomenon is referred to as membrane fouling.

Concentration polarization can be minimized by hydrodynamic means such as the feed flow velocity and the membrane module design. The control of membrane fouling, however, is more difficult. The transition between concentration polarization and fouling can be expressed by the concept of “critical flux.” This concept was introduced in the 1990s (Field et al. 1995; Howell 1995; Bacchin 2004), and it is the flux value below which a decline of flux with time does not occur, above it fouling is observed. Critical flux values depend on numerous parameters, such as properties of solutions to be treated (particle size, concentration, ionic strength, pH), surface interactions (zeta potential, surface tension), and hydrodynamic conditions (axial velocity)

(Bromley et al. 2002; Chen 1998; Ingmar et al. 1999; Belfort et al. 1994).

When operating below the critical flux, it is possible to observe a linear correlation between flux and transmembrane pressure. Above it, further increase in transmembrane pressures lead to additional layer deposit on the membrane surface, until a point where the deposit fully compensates the increase in pressure drop. At this stage the limiting flux is reached, which represents the maximum stationary permeation flux. After operating above the critical flux value, decreasing the transmembrane pressure will not lead to the previous flux behavior.

However, experimental evidences show that, although operating at subcritical flux, gradual fouling develops in membrane materials, and it proves to be hydraulically irreversible after a long period experimentation (Ognier et al. 2004).

The formation of a gel or cake layer is one cause for membrane fouling. Gel or cake layer formation may be caused by a variety of materials including inorganic precipitates such as CaSO_4 , Fe(OH) , and other metal hydroxides; organic materials such as proteins, humic acids, and other macromolecular materials; and biological components such as microorganisms and products of their metabolism (biofouling). Membrane fouling may also occur without concentration polarization, i.e., a direct transport to the membrane surface. The attachment of the substances to the membrane surface may be caused by adsorption due to hydrophobic interactions, van der Waals force attractions, or electrostatic forces. The fouling layer itself may be rather porous and thus permeable for aqueous solutions as some

inorganic precipitants or highly impermeable as some films of mineral oils or hydrophobic surfactants. The fouling mechanism depends also on the membrane process. In electrodialysis fouling is caused mainly by the precipitation of polyelectrolytes or sparingly soluble salts such as CaSO_4 or CaCO_3 . Membrane fouling in electrodialysis affects mainly the anion-exchange membranes because most of the colloidal and macromolecular polyelectrolytes present in natural waters such as humic acids or proteins are negatively charged. In ultra- and microfiltration of biological solutions, but also in reverse osmosis of sea water, biological fouling is a severe problem affecting the economics of the processes. In biomedical applications protein adsorption and protein denaturation at the membrane surface is often impairing the performance of the membranes. In membrane distillation, adsorption of molecules can change surface energy and hydrophobic properties.

The difference between concentration polarization and membrane fouling or scaling is illustrated schematically in Fig. 1.

Concentration polarization is a reversible process based on diffusion and takes place over a few seconds; it can be described adequately by a simple mathematical model and easily be controlled by the proper process design. Fouling is generally irreversible and the flux decline takes place over many minutes, hours, or even days. A constant flux is generally not reached at all. Membrane fouling is more difficult to describe and to control by experimental means. Membrane fouling is determined by a variety of different parameters including the feed solution constituents and their

Fouling, Fig. 1 Schematic diagram illustrating the difference between the flux decline due to concentration polarization and due to membrane fouling

Fouling, Fig. 2 Methods to reduce concentration polarization

concentration, membrane material, and the fluid dynamic system design. Membrane fouling can be caused by simple precipitation of insoluble materials or reversible and irreversible adsorption of components at the membrane surface and within the membrane pores.

The means of preventing or at least controlling membrane fouling effects are as heterogeneous as the different material and mechanisms causing the fouling (Ridgway et al. 1983; Nilson 1998). The main procedures to avoid or control concentration polarization and fouling involve:

- Pretreatment of the feed solution
- Membrane surface modifications
- Hydrodynamic optimization of the membrane module
- Membrane cleaning with the proper chemical agents

A list of various methods to reduce concentration polarization is reported in Fig. 2.

A pretreatment of the feed solution may include chemical precipitation, prefiltration, pH adjustment, chlorination, or carbon adsorption. In some membrane module, design concepts as, for instance, in hollow fiber modules, the

elimination of all particulate materials is of great importance for the proper function of the membrane.

Membrane surface modifications include the introduction of hydrophilic moieties or charged groups in the membrane surface by chemical means or plasma deposition.

Increasing the shear rate imposed by the feed solution on the membrane surface will in many cases reduce the membrane fouling. High feed flow velocities and the proper module design are efficient tools in controlling membrane fouling (Fig. 3).

When in spite of an adequate membrane and module design the membrane flux is decreasing with operation time to an unacceptable low value, it is necessary to clean the membrane to restore the flux in part or completely. Typical cleaning agents are acids and bases, such as HNO_3 and NaOH , complexing agents, enzymes, and detergents. Another very effective method to minimize the effects of membrane fouling in microfiltration is backflushing (Fig. 4). In backflushing, the applied pressure is reversed and the permeate is pushed through the membrane, lifting off fouling material that had been precipitated on the feed side membrane surface and washing it out of the filtration

Fouling, Fig. 3 Effect of axial velocity on concentration polarization

Fouling, Fig. 4 Backflushing method to reduce fouling

device. Backflushing is done in certain time intervals for a couple of seconds.

lifetime of metastable amorphous phase is strongly governed by the exact solution environment, with the presence of other additive molecules and ions, pH, ionic strength, and temperature affecting the lifetimes. The transformation of amorphous to crystalline hydroxyapatite is described by a first-order rate law and is only a function of pH of the mediating solution at constant temperature. Crystalline calcium phosphate apatite is less soluble in neutral and alkaline conditions and preferentially dissolves in acidic pH.

A calcium phosphate stability index based on the phosphate concentration, temperature, and pH (Kubo et al. 1979) helps to predict the threshold level of scaling (Filmtec 1995).

$$SI = pH_a - pH_c$$

where pH_a is the actual pH of a feed water and pH_c is the critical pH calculated as below:

$$pH_c = \frac{11.755 - \log(CaH) - \log(PO_4) - 2\log t}{0.65}$$

where CaH is the calcium hardness as ppm $CaCO_3$, PO_4 is the phosphate concentration as ppm PO_4 , and t is the temperature in $^{\circ}C$.

Phosphate can form a variety of polymeric ions and therefore many forms of phosphate salts are possible to be formed as a scale; however, the majority of calcium phosphate deposits are reported to be amorphous in nature (Chesters 2009). During membrane autopsy studies, calcium phosphate scaling was mostly observed as coprecipitated along with other organic and/or inorganic constituents (Fig. 1).

The state at which the calcium phosphate enters the RO system is expected to govern the nature of the deposit forming on the membrane surface (Ning and Troyer 2007). After pretreatment, if calcium phosphate is in its dissolved form, i.e., calcium and orthophosphate ions, then crystallization of calcium phosphate is more likely to occur on the membrane surface. On the other hand, if calcium phosphate is in its colloidal form, colloidal deposits are more likely to form on the membrane surface, instead of

Fouling due to Calcium Phosphate

Alice Antony and Pierre Le-Clech
School of Chemical Engineering, The University of New South Wales, UNESCO Centre for Membrane Science and Technology, Sydney, NSW, Australia

Calcium phosphate scaling occurrence is largely reported in reverse osmosis (RO) applications for the reclamation of wastewater (Chesters 2009; Greenberg et al. 2005; Zach-Maor et al. 2008). In municipal wastewater, phosphate levels typically range between 3 and 20 ppm, presenting a major operational challenge for systems designed to operate at high product recoveries. The crystalline forms of calcium phosphate are hydroxyapatite and fluorapatite, which are calcium orthophosphates with varying amounts of OH-, Cl-, and F-groups. Formation of hydroxyapatite occurs through autocatalytic solution-mediated transformation of highly unstable amorphous calcium phosphate, hydrolyzing rapidly to more stable hydroxyapatite microcrystals in water. The

Fouling due to Calcium Phosphate, Fig. 1 SEM-EDS images showing calcium phosphate scaling on RO membrane operated with paper mill effluent (Picture provided by Dr Alice Antony, The University of New South Wales, Australia)

crystallization. In these cases, antiscalants will be ineffective at their typical dosage levels, and therefore anticoagulants or dispersants should be added.

Unlike other scales, mitigating calcium phosphate scales through antiscalant addition is reported to be difficult (Greenberg et al. 2005; Ning and Troyer 2007). However, the risk of calcium phosphate precipitation can be minimized by maintaining the feed water below pH at 6.4 (Zach-Maor et al. 2008). Use of appropriate dispersants is an effective control measure when calcium phosphate is in the form of nanoparticles in the feed. The risk of calcium phosphate scaling can also be managed to a certain extent by reducing the concentration of orthophosphate, calcium, aluminum, iron, and fluoride at the pretreatment stage.

Combined Fouling Index (CFI); Membrane Fouling Index; Modified Fouling Index (MFI); Silt Fouling Index (SFI)

Membrane fouling is an inevitable phenomenon in membrane processes and reduces the efficiency and the economic viability of the membrane processes. All the fouling stages such as pore blocking and cake layer not only decrease the permeate flux during a membrane process but they could influence negatively the permeate quality. Understanding the membrane fouling means that it is possible to develop a method to measure and predict the fouling potential with respect to a membrane. There is a pressing need for a reliable method able to do that.

Simple membrane experiments such as Silt Density Index (SDI) and Modified Fouling Index (MFI) are fouling index methods used to evaluate the particulate fouling potential of a feed water on reverse osmosis (RO) and nanofiltration (NF) membrane process (Salinas-Rodriguez SG et al. 2015). The utilization of fouling indices enables to determine, e.g., the pretreatment requirements without conducting a pilot study which needs considerable time and expenses. Although these indices are the standardized parameters and widely used in engineering practices, they are considered to be unsatisfactory indicators that often fail to reflect the true fouling strength of the feed water.

SDI and MFI are performed using a membrane with 0.45 μm pores. The SDI test, defined by a standard method instructed in ASTM-D4189-07 (2014), is a dead-end filtration conducted on the feed at 207 psi through a 47 mm diameter microfiltration membrane with 0.45 μm pores. The rate of plugging is measured and expressed as % flux decline per minute. Fouling index by SDI is obtained by Eq. 1:

$$\text{SDI} = \frac{[1 - (t_i/t_f)]}{t} \cdot 100 \quad (1)$$

In Eq. 1, t_i is the initial time interval to collect 500 ml of permeate, and t_f is the final time interval to collect the same volume of permeate after a time interval t of 5, 10, and/or 15 min.

The limitations of the SDI test are well documented (Alhadidi et al. 2011; Rachman et al. 2013; Nahrstedt et al. 2008), and include: no correction for test water temperature; the result is

heavily dependent on the test membrane permeability; not applicable for testing high fouling feed water, e.g., raw water (ASTM recommends that turbidity should be <1 NTU); not applicable for testing UF permeate, which is increasingly being used in desalination pretreatment; no linear relation with colloidal/suspended matter; fouling potential of particles smaller than 0.45 μm is not measured; and it is not based on any filtration mechanism.

To overcome these deficiencies, the Modified Fouling Index using the same 0.45 μm membrane filters ($\text{MFI}_{0.45}$) was developed. The $\text{MFI}_{0.45}$ can achieve the linear relationship between concentration and flux decline, but still cannot accurately predict flux decline. Boerlage et al. (2002) confirmed that this is due to the fact that in RO, fouling is caused by smaller colloids that are not retained by the microfiltration membranes used in the MFI. Seeing the above complexities of fouling mechanisms, this is not unexpected. The $\text{MFI}_{0.45}$ test is similar to the SDI test (Schippers and Verdouw 1980), but the volume is recorded every 20 s for 20 min. It takes into account that initially pore blocking occurs, followed by cake/gel filtration, and finally cake/gel blocking and/or enhanced compression occurs. The cake filtration can be identified by plotting t/V versus V , where t is the time and V is the volume. The slope in this region is the fouling index. The obtained $\text{MFI}_{0.45}$ value is corrected for temperature and pressure and shows a linear relation with colloidal/suspended matter concentration. *MFI* is derived in Eq. 2, and it is defined as the slope of an inverse flow rate ($1/Q$) versus cumulative volume (V) curve:

$$\frac{1}{Q} = a + \text{MFI} \cdot V \quad (2)$$

Predicting the rate of fouling in RO systems based on the $\text{MFI}_{0.45}$ is possible, assuming that cake/gel filtration is the dominant mechanism. However, the predicted rate of fouling turns out to be very low for MFI of 1 s/L² (equivalent to SDI_{15} 1–3). A pressure increase of 1 bar is predicted to occur in more than 100 years with RO feed water with an $\text{MFI} = 1 \text{ s/L}^2$.

Both $\text{MFI}_{0.45}$ and SDI underestimate the fouling observed in practice.

As the SDI and the $\text{MFI}_{0.45}$ do not include smaller colloid sizes, a new index using an ultrafiltration (UF) membrane has been developed. Boerlage et al. tested this MFI-UF as a function of molecular weight cutoff (MWCO, 1–100 kDa) of the UF membranes and obtained values ranging from 2000 to 13,000 s/L2 (as compared to $\text{MFI}_{0.45}$ values of 1–5 s/L2). Higher values were linked to the retention of smaller colloids as well as cake filtration of the retained particles, although a correlation with the MWCO was not apparent. While other membrane characteristics may be partly responsible for those varied results, it is also important to note that fouling at such MWCOs is complex and cannot be solely attributed to particulates. A 13 kDa membrane was established to be the best membrane for such tests.

Boerlage et al. used a 13 kDa UF membrane (estimated pore dimension 9 nm) to measure fouling potential and effectiveness of pretreatment and compare the results with the SDI and the $\text{MFI}_{0.45}$. MFI-UF can be operated in constant flow or pressure mode. The MFI-UF values were in fact 400–1400 times higher than the $\text{MFI}_{0.45}$ due to the smaller particles captured. The MFI-UF can also be used to determine the effectiveness of pretreatment with regard to reduction of fouling potential. Roorda and van der Graaf (2001) used the MFI-UF to determine the fouling potential of UF membranes and confirmed the dependence on membrane type. As a general evaluation, Reiss and Taylor compared three parameters used to investigate fouling: the Silt Density Index (SDI), the Modified Fouling Index (MFI), and the linear correlation of the water mass transfer coefficient (MTC). Three different NF pilot systems were used with different pretreatments including activated carbon and MF. No correlation between the different parameters was obtained, indicating that the filtration laws on which the models are based might not be valid for NF. Hence, these parameters need to be used with caution.

SDI and MFI seem to be difficult if there is more than one type of fouling mechanisms. Another approach to estimate fouling potential

due to various fouling mechanisms is attempted by combining MFI values measured using multiple test membranes. This method, which is designated as the Combined Fouling Index (CFI), allows considering the contribution of particles, hydrophobic matters, colloids, and organics to RO/NF fouling at the same time. J.-S. Choi et al. (2009) used three different membranes: a hydrophilic microfiltration membrane, a hydrophobic microfiltration membrane, and a hydrophobic ultrafiltration membrane in order to study the efficiency of different pretreatments. The Combined Fouling Index value was obtained using Eq. 3:

$$\text{CFI} = \omega_1 M_1 + \omega_2 M_2 + \omega_3 M_3 + \omega_4 \quad (3)$$

where M_1 , M_2 , and M_3 are the MFI values of the three membranes and ω_1 , ω_2 , ω_3 , and ω_4 are weighting factors depending on the characteristics of RO/NF membrane because they are closely related to fouling mechanisms. The weighting factors were calculated from the flux decline rate of each membrane.

CFI values are in good agreement with nanofiltration flux decline because with this test is possible considering the impact of different foulants.

In addition, it is also possible to use more than three test membranes to obtain more information on the characteristics of feed water.

²Key Laboratory for Green Chemical Technology of Ministry of Education, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

Fouling release is one of the general strategies to achieve desired non-fouling surfaces. Any surface immersed in a specific aqueous system (wastewater, seawater, tap water, etc.) is subjected to the undesirable settlement and nonspecific adsorption of biomolecules (e.g., protein and polysaccharide), natural organic matter, hydrocarbon, and microorganism (e.g., bacteria, algae, and mollusks), known as fouling. Non-fouling surfaces to resist different foulants are vital in a wide range of applications including chemical separation and purification, drug delivery systems, biomaterials, biosensors, and marine coatings. The concept of fouling release initially comes from marine non-biocidal coating. Fouling release refers to the feature that the attached and

adhering foulants are more easily removed from the depositing surfaces at low hydrodynamic shear forces due to the weakened interfacial bond between the synthetic surface and different foulants, promoting adhesive failure. The release ability of foulants is proportional to the surface energy and modulus (gE)^{1/2} (Brady and Singer 2000). The lower the surface energy and modulus, the stronger reduction of the enthalpy of adsorption and the higher fouling release potential of the surface. Surface with compositional heterogeneous hydrophobic/hydrophilic domains can also reduce interactions with the bioadhesives. In the design of surfaces to eliminate the adhesion of various foulants, polysiloxane- and fluorinated polymer-based surfaces are usually hydrophobic and most effective in reducing adhesion. The major advantage of polysiloxane-based surfaces is the synergy between low surface energy (to minimize the work of adhesion) and low elastic modulus. The major advantage of fluorinated polymer-based surfaces lies in hydrophobicity and oleophobicity with low surface energy.

Marine non-fouling coatings provide a source of inspiration for fouling release membrane. Membranes with fouling release property are essential for preventing fouling growth on the surfaces whose antifouling performance relies on the low adhesion strength and easy release of foulants on such a membrane. In recent years, surface modification of membranes using low surface energy materials to enhance fouling release ability is under active studying microfiltration, ultrafiltration, nanofiltration, reverse osmosis, etc. The surface energy and heterogeneities are introduced in the elucidation of membrane fouling release mechanism during membrane filtration. The lower surface energy and larger chemical heterogeneity correspond to a lower driving force for the adsorption of the foulants, thereby resulting in effective fouling release ability. Surfaces which fulfill these requirements are often derived from polysiloxane- and fluorine-based polymers. In situ forced surface segregation of amphiphilic copolymers and grafting low surface energy molecules or monomers to already formed membranes are popular methods to fabricated

fouling release membrane. Membranes with low surface energy chains (such as PDMS, poly(ethylene glycol)-fluoropolymers, perfluoroalkyl polymers, perfluoropolyether polymers, and fluorine-containing block) showed a high release rate. The release rates of PDMS and perfluoroalkane polymer-functionalized membranes are about five times higher than those of hydrophilic surface as a result of the low interaction between the low surface energy surfaces and protein (Thérien-Aubin et al. 2011). There is a growing body of evidence that amphiphilic or chemically heterogeneity membrane surfaces can present both low surface energy and high hydration energy microdomains and show promising performance against a wide range of foulants. Membrane prepared from amphiphilic copolymers with hydrophilic segments and fluorine-containing segments via nonsolvent-induced phase separation (NIPS) process through forced surface segregation showed enhanced oil, protein, and bacteria release ability (Chen et al. 2011). The low surface energy microdomains on the membrane surface minimize the intermolecular forces of interactions (polar or and hydrogen-bonding interactions) between the foulants and the membrane surface, remarkably reducing the flux decline and reducing energy consumption during the dynamic filtration process.

In the application of antifouling membranes for water treatment and biomedical application, fouling release membranes offer an interesting alternative to environmentally friendly strategies to facilitate foulants removal, such as hydrocarbon substances, biomolecules, and microorganisms.

Fouling Release Membranes

Zhongyi Jiang¹, Xueting Zhao¹, Jinming Peng², Yanlei Su¹ and Hong Wu¹

²Key Laboratory for Green Chemical Technology of Ministry of Education, School of Chemical Engineering and Technology, Tianjin University, Tianjin, China

Fouling release membrane is a novel kind of membrane that has the chemical structure and main feature of nonpolar low surface energy microdomains and hydrophilic domains, inhibiting the nonspecific adsorption of a variety of foulants. The low surface energy microdomains on the membrane surface, which can be constructed with silicone- and fluorine-based polymers, are used to minimize the intermolecular forces of interactions (polar and/or hydrogen-bonding interactions) between the foulants and the membrane surface. The hydrophilic domains are used to bind water molecules and generate hydration layer similar with widely popular hydrophilic modification methods. Considering that foulants tend to adsorb on traditional hydrophobic membrane surfaces driving by the decrease of the Gibbs free energy of the system, the surface energy of membranes is regarded as one of the most relevant physicochemical parameters influencing free energy of the adsorption process. The reduction of the surface energy causes a strong reduction of the enthalpy of adsorption which describes the strength of interaction between the protein and the surface and thus strongly decreases the driving force for the foulants to adsorb to the surface (Worz et al. 2012). Due to the presence of nonpolar low surface energy microdomains on the membrane surface, foulants in the feed solution can easily release from the membrane surface and diffuse back to the bulk feed solution during the dynamic membrane filtration process. Inspired by marine fouling release materials, this kind of membrane is

Fouling Release Membranes, Fig. 1 Tentative illustration of the flux decline resistant mechanism of membranes (Chen et al. 2011b)

initially designed to detach the foulants from the surface at low hydrodynamic shear force, and now it is applied to achieve low permeation flux decline and high permeation flux recovery simultaneously during the membrane filtration process.

To construct fouling release membrane surface, majority of the existing researches have been carried out to reduce the surface free energy through fluorine-based polymers. In situ forced surface segregation and post-surface grafting are the two general surface modification methods being explored to introduce low surface energy microdomains onto the membrane surface. In the process of the forced surface segregation, amphiphilic copolymers with hydrophilic segments and fluorine-containing segments are used as additives or polymer membrane materials as that usually applied in surface segregation approach. Considering that fluorine-containing segments

are not able to spontaneously segregate onto the polymer-water interface due to the unfavorable thermodynamics, the forced surface segregation coupled with nonsolvent-induced phase separation process is proposed for achieving membrane surfaces with fluorine-containing microdomains. In the immersion-precipitation step, hydrophilic segments of the copolymers segregate to the polymer-water interface freely and drag the fluorine-containing hydrophobic segments to enrich on membrane surfaces. Both the composition of hydrophilic and hydrophobic segments and the volatility of casting solvent can affect the surface segregation behavior and the fouling release ability of membrane surfaces (Chen et al. 2011a, b). The membrane materials used in the post-surface grafting method must be rich of reactive groups. Surface grafting by chemical reaction is a facile method for introducing low surface energy microdomains onto hydrophilic

membrane surfaces. Low surface energy perfluoroalkyl or even polysiloxyl molecules with active groups are used as modifiers to improve the fouling release ability of membrane (Thérien-Aubin et al. 2011; Zhao et al. 2012).

Although hydrophilic surface modification can significantly enhance the antifouling property of the membrane, it, unfortunately, often results in a drastic flux decline during the separation and purification process. Fouling release membrane is an alternative to traditional hydrophilic membrane which leads to lower permeation flux decline. Figure 1 reports a tentative flux decline resistant mechanism of fouling release membrane. The random presence of nonpolar low surface energy (typically fluorinated) microdomains on the hydrophilic membrane surface creates a surface with chemical heterogeneity that is vital to constructing a truly fouling release membrane surface. At moderate shear rate along membrane surface, nonpolar low surface energy microdomains prevent the coalescence, migration, and spreading of the hydrophobic oil droplets or limit the accumulation/coalescence of polar biofoulants, thus endowing the membrane surface with outstanding fouling release potential without inducing a flux decline.

Fractional Free Volume (FFV)

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, Russia

Fractional free volume (FFV) is an empirical dimensionless parameter that characterizes free volume in polymers. FFV can be defined as the ratio V_f/V_{sp} , where V_f (cm³/g) is the free volume and V_{sp} (cm³/g) is the specific volume of the polymer, the latter parameter being the reciprocal density ρ . The value of V_f can be calculated using Bondi (1968) formula $V_f = V_{sp} - V_{oc}$, where V_{oc} is the occupied volume, and it can be estimated as $V_{oc} = 1.3 V_w$, where V_w is van der Waals volume of the repeat unit of the polymer. Such an estimate gives the FFV values of most polymers in the range of 10–25 %. However there are examples when FFV is as large as 35 % (polytrimethylsilyl propyne). In spite of its wide usefulness, such definition of FFV has many disadvantages and is being often criticized. In the case of glassy polymers, the density may depend on prior history of the sample and, to some extent, on the method of determination. The coefficient 1.3 in calculating V_{oc} is estimated from packing density of molecular crystals at 0 K and cannot adequately describe polymers at room temperature. In addition, calculation of V_w of a repeat unit as the sum of the increments of van der Waals volumes of atoms that form this repeat unit can lead to some inaccuracies. Since this approach poorly takes into account the dead volume which depends on conformations of the chain and is different for different gases, quantum chemical corrections are desirable. More reliable results were reported by Ronova et al. (2003). So FFV found in this way can be considered as a semi-quantitative parameter suitable for comparison of series of polymers. Park and Paul (1997) assumed that FFV can be considered not as a universal property of polymers. Gases with

different molecular dimensions can “feel” different parts of the size distribution of free volume. So an empirical method for calculation of occupied volume specific for each gas was proposed. This group contribution method allows better predictions of the permeability coefficients based on modified FFV.

Positron annihilation lifetime spectroscopy (PALS) also allows an estimation of fractional free volume as $FFV = Nv_f$, where N is hole number density (concentration of holes) and v_f is the mean volume of the spherical hole with the radius R in the polymer or $v_f = 4/3 (\pi R^3)$. The FFV values found in this manner are usually smaller than FFV estimated via Bondi by a factor 3–4. It is explained by the fact that a big fraction of size distribution of free volume in polymers consists of holes with the radii inaccessible to o-positronium having the size of 1.06 Å. This is confirmed by the calculations using molecular dynamics method (Hofmann et al. 2002): extrapolation of FFV to the zero radius of probe results in FFV values much greater than those found via PALS.

Fractionation of Fish Protein Hydrolysates

Marie-Pierre Belleville

Institut Européen des Membranes (IEM): UMR CNRS 5635, Université de Montpellier II, Montpellier, France

Each year the processing industry of marine species generates large amounts of solid by-products such as filleting wastes, heads, etc. which are usually converted to fish meal and oil for feed. However, these by-products often contain high concentrations of proteins that can be transformed into peptides through enzymatic hydrolysis. Fish protein hydrolysates (FPH) possess good nutritional properties and biological activities such as antioxidative, anticarcinogenic, immunological activities, etc. (Chalamaiah et al. 2012). They can thus represent marketable and value-added products to be used as food and feed. Although biological properties of peptides are related to various characteristics, molecular weight (MW), amino acid sequence, hydrophobicity, charge, and acidobasic character, the MW seems to be one of the most important ones. In particular peptides with MW between 1 and 4 kDa have been identified as the most bioactive ones (Hsu 2010). The pressure-driven membrane processes thus appear to be good candidates to fractionate and concentrate FPHs in view to produce peptide fractions with high specific activity. Firstly peptides can be separated from nonhydrolysed proteins owing to UF with high molecular weight cutoff (MWCO) membranes (~20 kDa). Then peptide hydrolysates can be fractionated according to their size with UF membranes of intermediate MWCO (4–8 kDa); the recovery yields are improved if UF is combined with diafiltration. Finally the concentration of selected fractions can be carried out with nanofiltration (NF) membranes of low MWCO (200–300 Da) (Chabeaud et al. 2009; Vandanjon et al. 2009). Figure 1 shows the molecular weight distribution of different peptide fractions obtained after UF/NF fractionation of a tuna dark muscle hydrolysate.

Fractionation of Milk by Membrane Operations

Marie-Pierre Belleville

Institut Européen des Membranes (IEM): UMR CNRS 5635, Université de Montpellier II, Montpellier, France

Milk is a complex colloidal suspension containing many classes of different size components (salts, soluble proteins, casein micelles, fat globules, microorganisms, etc. (see Table 1)) which can be well separated from others according to their size or charge, thanks to membrane techniques (Brans et al. 2004; Pouliot 2008; Gésan-Guiziou 2010).

Since the 1980s, ultrafiltration (UF) has been widely used in dairy industries in order to concentrate the protein fraction of milk without any denaturation. This operation is generally carried out on spiral wound polymer membranes or to a lesser extent on tubular ceramic membranes with molecular weight cutoff (MWCO) 10–50 kDa and at a transmembrane pressure of 200–400 kPa. According to the concentration level, different types of concentrate can be distinguished. UF of skimmed milk with low volume reduction factors (VRF up to 1.7 (the ratio between either the

volumes of feed and retentate in discontinuous mode or flow rates of feed and retentate in continuous mode)) leads to the protein standardization of both drinking and cheese milks. The use of such milks permits a better process control of continuous cheese-making processes and leads to a constant quality of products throughout the year. The use of intermediate-concentrated retentates ($1.7 < \text{VRF} < 5$) and high-concentrated retentates (VRF 5–7) permits the continuous production of numerous cheese varieties (fresh unripened cheeses, soft and semihard cheeses) with high yield and very little whey drainage. All these cheese-making processes are derived from the famous worldwide process known as MMV process after the investigators Maubois, Mocquot, and Vassal (Gésan-Guiziou 2010).

Microfiltration (MF) is an alternative to centrifugation for the removal of bacteria and spores from skimmed milk in order to extend its shelf life without applying a time-temperature treatment. MF is thus carried out with multichannel ceramic membranes with a pore diameter of 1.4 μm at high tangential velocity ($6\text{--}9 \text{ m s}^{-1}$) and low transmembrane pressure (TMP) (50 kPa). In order to limit the fouling phenomena, a uniform TMP is applied all along the membrane, thanks to the circulation of the permeate cocurrent of the retentate (Bactocatch system[®], AlphaLaval; Invesys[®] APV) or thanks to the use of ceramic membranes with linear hydraulic-resistance gradient (GP Membralox[®] membrane Pall-Exekia; Isoflux[®] membranes Tami-Industries). MF of skimmed milk on a 0.2 μm ceramic membrane permits the concentration of casein micelles. One hundred percent of the caseins are recovered in the retentate without any denaturation, while the permeate which is sterile and free of phage particles presents a composition close to that of whey. It can be used to prepare whey protein concentrate (WPC) and isolate (WPI). Finally MF can be also used for the separation of milk fat into small ($< 3 \mu\text{m}$) and large ($> 5 \mu\text{m}$) globules. This operation is achieved with ceramic membranes with nominal pore size higher than 2 μm . The permeate which is enriched in small globule fraction leads to the production of cheeses with smoother and finer texture.

Fractionation of Milk by Membrane Operations, Table 1 Approximate composition of milk

Components	Concentration (g L ⁻¹)	Size (μm) or molecular weight (Da)
Water	870–875	
Fat	34–44	0.15–15 μm
Lactose	48–50	342 Da
Proteins	32–35	
Caseins (micelles)	25–28	50–500 μm
Soluble proteins	5–7	14.2–150 kDa
Ashes (mineral and salts)	8–9

Fractionation of Whey by Membrane Operations

Marie-Pierre Belleville

Institut Européen des Membranes (IEM): UMR CNRS 5635, Université de Montpellier II, Montpellier, France

Whey is a coproduct of cheese-making and casein manufacture in the dairy industry; it is the liquid drained from the curd obtained after addition of rennet (chymosin) or mineral/organic, or the permeate obtained during skimmed milk microfiltration (MF) in view of casein concentration. Whey contains many classes of different-size components (salts, lactose, soluble proteins (mainly β -lactoglobulin and α -lactalbumin), residual casein, microorganisms, etc. (see Table 1)), but its composition depends on the cheese-making process. The addition of enzyme or rennet milk leads to sweet whey (pH 6.2–6.4), whereas acid whey (pH 4.6–5) is obtained after acidic coagulation of milk. Considered as waste for years, whey is now widely used as food ingredients in many goods and infant and dietetic foods. Owing to chromatographic, electrodialytic, and membrane techniques which permit whey fractionation, it is possible to prepare valuable proteins and peptides with high nutritional qualities (high biological value (BV), amino acid profile, etc.), interesting physical properties (gelling,

Fractionation of Whey by Membrane Operations, Table 1 Approximate composition of sweet and acid whey

Components	Sweet whey (%)	Acid whey (%)
Water	93–94	94–95
Lactose	4.5–5	3.8–4.3
Lactic acid	Traces	Up to 0.8
Fat	Traces	Traces
Total proteins	0.8–1.0	0.8–1.0
Soluble proteins	0.6–0.65	0.6–0.65
Ashes (mineral and salts)	0.5–0.7	0.5–0.7

foaming, water binding, etc.), and physiological functionalities.

Whey protein concentrates (WPC) containing 35–85 % protein are prepared by ultrafiltration (UF) with 10–20 kDa molecular weight cutoff (MWCO) membranes. According to the concentration level, different types of concentrate can be distinguished. For 35 % WPC, the volume reduction factor (VRF) – the ratio between either the volumes of feed and retentate in discontinuous mode, or flow rates of feed and retentate in continuous mode – is about 4–7, whereas VRF of 13–50 are required to prepare 50–60 % WPC. 75–85 % WPC are obtained owing UF (VRF 30–35) combined with diafiltration in order to remove minerals and lactose. Whey protein isolates (WPI) containing more than 90 % of proteins are generally produced from the microfiltration permeate of skimmed milk using ion-exchange chromatography (IEC).

Reverse osmosis (RO) permits the concentration of whey and its derivatives before dehydration. Compared to vacuum evaporation, the energy consumption is lower, however, the concentration level is limited to about 25–28 % dry matter (VRF 4) due to the increase of osmotic pressure and viscosity and in order to avoid salt precipitation and lactose crystallization.

As the high salt content of whey decreases its nutritional value and generates processing difficulties, demineralization of whey is carried out before drying. Electrodialysis (ED) and/or ion-exchange chromatography (IEC) are currently

used to achieve demineralization of whey in the range 50–90 %. However, as the whey to be demineralized should be previously concentrated by RO, these techniques involve high investment and running costs and generate large volumes of polluting effluents. On the contrary, nanofiltration (NF) appears to be more attractive even if this process leads to a lower level of demineralization. NF permits to concentrate and demineralize the whey simultaneously at low transmembrane pressure. The process is thus more cost-effective and environmentally friendly compared to ED and IEC. In addition, as nutrition value ions such as calcium are more retained by the membrane than monovalent ions (such as Cl^-), the final products show higher nutritional and technological properties.

Fractionation of White Wine Proteins by Membrane Operations

Johannes De Bruijn

Department of Agroindustry, Food Engineering Group, Universidad de Concepcion, Chillan, Chile

Fractionation is a separation process in which a certain amount of a mixture is divided up into a smaller number of quantities or fractions with different molecular composition. Fractionation is based on the difference in specific properties between the individual components. Commonly equilibrium has to be aimed between the recovery of a specific compound and the desired purity of each fraction.

Proteins from white wines differ in molecular weight, ranging from 9 to 72 kDa, isoelectric point with pI between 3 and 9, hydrophobicity, degree of glycosylation, and thermal stability. Proteins can exhibit positive effects such as the stabilization of foam in sparkling wines, the interaction with aroma compounds, the protection of wine against precipitation of tartaric salts, and the interactions with other wine compounds such as

ethanol, polyphenols, and polysaccharides. However, they are also involved in some aspects that can impair the acceptance of the final product by consumers, such as haze formation during bottle storage and wine allergy (Ferreira et al. 2002). Therefore, several fractionation methods have been developed to achieve a selective separation of wine proteins.

First some preparative separation methods are often used such as dialysis (3.5 kDa cutoff membranes) to eliminate low molecular weight compounds, ultrafiltration (10 kDa cutoff membranes) to isolate and concentrate proteins, or protein precipitation by adding high concentration of salts (ammonium sulfate) or organic solvents (ethanol, methanol, or acetone). Afterwards, several chromatographic, electrophoretic, and membrane separations are usually combined that results into enriched protein fractions. A number of different chromatographic techniques, such as ion exchange, gel filtration/size exclusion, hydrophobic interaction, affinity, and chromatofocusing, have been developed for the fractionation and purification of wine proteins. In addition to chromatographic techniques, electrophoresis such as capillary electrophoresis and capillary gel electrophoresis can be used to achieve protein fractionation on a preparative scale (Le Bourse et al. 2010).

Sequential fractionation of white wines (Fig. 1) by using a series of ultrafiltration membranes with decreasing molecular weight cutoff ranging from 300, 100, 30 to 10 kDa allows to study foam stability of champagne wines (Abdallah et al. 2010) and protein haze stability of white wines (De Bruijn et al. 2011a, b). Ultracel PLC membranes of composite regenerated cellulose within a stirred frontal cell or a cross-flow unit should be preferred due to their ultralow protein binding capacity. Although the purity of protein fractions improves during membrane fractionation, a decrease of protein stability has been observed due to the retention of high macromolecular species (glycoproteins superior of 100 kDa) by the ultrafiltration membrane. This changing composition of the wine matrix makes membrane fractionation a complex process.

Free Diffusion

Karel Friess
 Department of Physical Chemistry, University of Chemistry and Technology Prague, Prague,
 Czech Republic

Free diffusion is a random nonrestricted walk or shift of atoms, ions, or particles on distances higher than those of the interatomic ones. From the atomistic point of view, diffusion is considered

as a result of the random walk of the diffusing particles, self-propelled by thermal energy (Brownian motion); from the phenomenological (macroscopic) point of view, such (diffusion) flux, which can be described by Fick's laws, is proportional to the minus gradient of chemical potential and goes from regions of higher concentration to regions of lower concentration of diffusant in appropriate (motionless) environment or solvent till concentration equalizing. From thermodynamic point of view, diffusion (mixing) in chemical system increases its entropy (a rate of disorder) and tends to state with the lowest inner energy.

An example of free diffusion is as follows (see Fig. 1). If we consider infinite cylinder of unit cross section, not with an instantaneous plane source at $x = 0$, but with an initial distribution of concentration given by $c = c_0$ for $x < 0$ and $c = 0$ for $x > 0$, at time $t = 0$, solution of the *Fick's second law* in the one-dimensional case (coordinate x) after several treatment steps and substitutions gives a solution in the form (Jost 1960; Cranck 1975)

$$c = \frac{c_0}{2} \left[1 - \operatorname{erf} \left(\frac{x}{2\sqrt{Dt}} \right) \right] \quad (1)$$

where $\operatorname{erf} x$ is Gauss error function ($\operatorname{erf}(-x) = -\operatorname{erf}(x)$; $\operatorname{erf}(\infty) = 1$) and D is a diffusion coefficient. Thus, with if we imagine at $t = 0$ in cylinder (column) one solution with diffusing species with its concentration $c = c_0$ (at $x < 0$) and a second solution (pure solvent) with $c = 0$ (at $x > 0$) given in contact (with sharp

Free Diffusion,

Fig. 1 Schematic draw of free diffusion with two solutions: a change of concentration profile in time given by Eq. 1 from time $t = 0$ (left) to $t = \infty$ (right)

interface at $x = 0$). If such system is kept at stable conditions (constant temperature and no vibrations from outside which could cause convection), at times $t > 0$ a former sharp interface tends to vanish due to diffusion between both solutions, and at long times ($t = \infty$) concentration in the whole system became identical and is equal to the half of the initial concentration $c = c_0/2$.

Free NaA Stabilized Sodalite (SOD)

Catia Algieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Sodalite (SOD) is a small-pore (2.8 Å) zeolite and so good candidate in the separation of small molecules such as NH_3 (2.55 Å), He (2.6 Å), H_2O

(2.65 Å), and H_2 (2.95 Å) from gas or liquid mixtures (Khajavi et al. 2007). In 1969 aluminosilicate sodalite was first synthesized using tetramethylammonium as structure directing agent (SDA) (Baerlocher and Meier 1969). For the first time, Bibby and Dale successfully reported the synthesis of silica sodalite (Bibby and Dale 1985). They prepared silica sodalite using a nonaqueous solvent. In particular, the ethylene glycol was used as solvent and SDA and the unit cell composition obtained was $\text{Si}_{12}\text{O}_{24} \cdot 2\text{C}_2\text{H}_4(\text{OH})_2$. Subsequently, it demonstrated the possibility to prepare silica sodalite by using SDA 1,3,5-trioxane (Keijsper et al. 1989). Recently, Yang and coworkers studied the effect of water in a solvothermal system composed of SiO_2 , NaOH, and ethylene glycol. They discovered a little amount of water did not influence the sodalite crystallization (Yang et al. 2007). However, when the water molar exceeds the silica one, the a-quartz phase was synthesized. The authors also demonstrated the addition of germanium into the system accelerated the crystallization of SOD. These and other SDAs (Braunbarth et al. 1997; Werthmann et al. 2000) can be used to synthesize sodalite crystals. However, for each SDA the optimization of the synthesis conditions is required above all the temperature that can be varied from

some days to different weeks (Münzer et al. 2008). Considering the pore size of this zeolite, different research groups tried to prepare sodalite membranes for the separation of small molecules. For example, low silica SOD membranes were prepared by microwave-assisted hydrothermal synthesis (Julbe et al. 2003). The prepared membranes exhibited a low He/N₂ permselectivity (6.2) owing to the presence of intercrystalline defects into the zeolite layer. Recently, defect-free supported hydroxy sodalite membranes were hydrothermally synthesized on alumina disk and used in pervaporation (Khajavi et al. 2010). The membranes exhibited exceptional acid and base stability within a pH range of 2.7–13.7 as confirmed by the very high water selectivity values (1,000,000) and stable fluxes.

Free Protons in Solid Heteropoly Compounds

Ubavka B. Mioč

Faculty of Physical Chemistry, University of Belgrade, Belgrade, Republic of Serbia

The basic structure of hetropoly acid hydrates (HPAs·nH₂O) has already been determined by Keggin (1934), but the water and hydrated proton entities filling the channels (secondary structure) have not been studied much until the early 1990s. As heteropoly acids are superionic proton conductors at room temperature and good catalysts, it is clear that their activities will be the function of hydration degree and dynamics of proton species. Therefore, it was necessary to focus on the studies that identify protonic entities and follow their dynamics. The studies started on WPA-6, the most stable hydrate of WPA with well-known structure. Crystallographic results for WPA-6 show that Keggin's anions in WPA-6 are stabilized by dioxonium ion H₅O₂⁺, which was defined as planar and rigid (Brown et al. 1970). On the other hand, IR and Raman spectra taken at room temperature have shown that different protonic species (H₅O₂⁺, H₃O⁺, H₂O) exist in dynamic equilibrium (Mioč et al. 1991, 2005; Colombari and Tomkinson 1997):

Spectroscopic results have also shown that dioxonium ion is not rigid, and even more, four conformation forms of the H₅O₂⁺ have been found (Kremenović et al. 2002). Theoretical ab initio calculations have proved that too (Mioč et al. 2008).

Finally, to confirm the proposed equilibrium, incoherent inelastic neutron spectra (IINS) were measured (Mioč et al. 1994; Fig. 1). Spectra of WPA-6 show that all bands characteristic of the abovementioned protonic species are present in IINS spectrum (Fig. 1a), and results are in accordance with literature data (Jones et al. 1989;

Free Protons in Solid Heteropoly Compounds,

Fig. 1 IINS spectra of WPA-6 (a), WPA-1 (b), WPA-0.2 (c), and WPA-D (d) (Reprinted with permission of Elsevier)

Free Protons in Solid Heteropoly Compounds,

Fig. 2 Compton profile of proton. Momentum distribution of single proton. Solid line for WPA-6 and dotted for WPA-0 (Reprinted with Permission of Elsevier)

Kearley et al. 1990; Tomkinson 1992). Changes in IINS spectra during the process of calcinations of WPA-6 are also evident (Fig. 1). When dehydration is completed, only protons stabilize the Keggin's structure, as was postulated. The IINS spectrum of WPA-0.2, calcinated at about 300 °C, was characterized by three main bands at 1149 ($0 \rightarrow 1$), 2287 ($0 \rightarrow 2$), and 3341 cm^{-1} ($0 \rightarrow 3$). The single strong band in the spectrum of the dehydrated phase at $1,149 \text{ cm}^{-1}$ was assigned to a proton centered within a symmetric (octahedral) environment of oxygen atoms. The obtained spectrum is very similar to that observed for manganese oxide ($\gamma\text{-MnO}_2$) where Fillaux identified “free protons”/“proton gas” for the first time (Fillaux et al. 1991).

Some additional neutron measurements were done at Rutherford Appleton Laboratory on the VESUVIO installation with high-energy (few eV) neutrons, with the aim to get more information about proton dynamics. From Fig. 2, it is evident that Compton scattering of protons takes place in the attosecond time scale. The “free protons” present in WPA-6 and those remaining in WPA-0.2 have a different single-proton momentum distribution (Fig. 2).

Using Born-Oppenheimer approximation (Chatzidimitriou-Dreismann et al. 2002), kinetic energy of chemical covalent bond formations was calculated in WPA-6 and WPA-0.2: E_{kin} (WPA-6) = 174 meV and E_{kin} (WPA-0.2) = 231 meV. Results show that protons are more spatially localized in WPA-0 than in WPA-6 phase on the time scale of 10^{-14} s. Ratajczak et al. discussed the obtained neutron results and compared them with those of

Kozhevnikov obtained by ^{17}O NMR spectroscopy (Ratajczak et al. 2001, pp. 100–117). Kozhevnikov (1998) speaks also about over-coordinated protons in case of HPAs but in tetrahedral surrounding of oxygen atoms. He has emphasized the important role of “free protons” in acid catalysis. A short time later, Essayem also discusses the role of “free protons” in acid catalytic processes and activity of Cs-WPA salt ($\text{Cs}_{1.5}\text{H}_{1.1}\text{PW}_{12}\text{O}_{40}$) (Essayem et al. 2000). Some other authors, as Janik et al. (2004), also speak about “free protons” and deprotonated water formed from protons and few oxygen atoms from Keggin's anions. Recently, Ph. Colomban continues to emphasize the importance of protons in solids (Ph. Colomban 2013). It could be said that nowadays the idea of “free protons” in solids is accepted in the scientific community.

Ratio of $\text{H}^+/\text{H}_2\text{O}$ and $\text{H}_3\text{O}^+/\text{H}_2\text{O}$ is also very important for conductive characteristics of these compounds as charge carriers and species forming networks of hydrogen bonds responsible for fast proton transport, i.e., high proton conductivity (Table 1). Many things could be analyzed from data concerning proton conductivity: influence of degree of hydration, influence of protonic ratio, and influence of big cations, in the case of salt on water dissociation. It is evident that cation parameters influence both the host lattice and rearrangement of protonic entities and their dynamics. In the last row are some data for $\text{KH}_2\text{PW}_{12}\text{O}_{40} \cdot 7\text{H}_2\text{O}$ (KH_2WPA) which have been used as PEM in H_2/O_2 fuel cell with very promising results (Holclajtner-Antunović et al. 2010).

KH ₂ WPA·7H ₂ O	1.0·10 ⁻²
(t = 80 °C; RH = 70 %)	

The existence of different protonic species in HPCs·nH₂O was confirmed by dielectric measurements from Cole-Cole diagrams ($\epsilon'' = f(\epsilon')$) too. Debye's type relaxation times were determined in two frequency regions: from 5 to 500 kHz and in microwave region from 8 to 12 GHz. The relaxation time of 1.0×10^{-10} was assigned to the reorientation H₃O⁺ ion and/or H₂O molecules; and relaxation time of 1.6×10^{-8} s was ascribed to the H⁺ and/or H₃O⁺ reorientation and that 1.0×10^{-11} to proton jumps (Tjapkin et al. 1993). With temperature increase, the relaxation times are changing in function of proton entities participated in dehydration process.

Whatever we call protons in solids, “free protons,” “proton gas,” or over-coordinated protons, it is a special, new state of protons in solids, not only in HPCs, forming covalent bonding on a time scale of 10^{-13} to 10^{-15} s, which determines their catalytic and conductive characteristics.

Free Radical Polymerization

► Surface Modification: Wet Chemical Oxidation

Free Volume Distribution, Fig. 1 Size distribution (MD) of free volume in 6FDA-3MPD polyimide accessible for o-positronium probe (Adopted from Heuchel et al. (2004))

Free Volume Distribution

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, Russia

Size distribution of *free volume* in glassy membrane materials is accessible to estimation by computer simulations (*molecular dynamics*, MD) and to experimental studies by the probe methods. In low permeable and highly selective conventional glassy polymers like polyimides, size distribution of free volume elements (microcavities), according to MD, is located within the range of microcavity radius 1–5 Å and can be represented by the Gauss function (Heuchel et al. 2004) (see Fig. 1). For polymers with greater gas permeability such as *poly(trimethylsilyl propyne)* (PTMSP) or amorphous Teflon AF, according to MD, it is much wider and extends up to microcavity radius 10–12 Å (Hofmann et al. 2003) (see Fig. 2). *Positron annihilation lifetime spectroscopy* (PALS) also indicates widely distributed sizes of free volume in highly permeable polymers. However, there are two interpretations of wide size distribution. According to Shantarovich et al. (1993)

Free Volume Distribution, Fig. 2 Size distribution (MD) of free volume in PTMSP accessible for o-positronium probe (Adopted from Hofmann et al. (2003))

Free Volume Distribution, Fig. 3 Size distribution (PALS) of free volume in PTMSP (Adopted from Hofmann et al. (2002))

and Consolati et al. (1996), lifetime distribution can be represented by bimodal size distribution (Fig. 3), while Dlubek (2008) proposed to consider monomodal size distribution with variable dispersion. Both approaches are consistent with the results of MD simulation.

Free Volume Element

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical
Synthesis, Russian Academy of Sciences,
Moscow, Russia

Free volume element (FVE) (synonyms: microcavity, hole) is a conditional notion used for description of free volume in polymers (mainly in glassy polymers). Thus, in the positron annihilation lifetime spectroscopy (PALS) (Shrader and Jean 1988; Bartos 2000), it is defined as a sphere with the diameter R estimated using the Tao-Eldrup equation (Tao 1972; Eldrup et al. 1981) via the o-positronium lifetimes τ_i . In this approach it is conceived that polymer can be considered as a continuous matrix with uniformly distributed in it spheres with the size $4/3(\pi R^3)$. It was also assumed that cylindrical shape of FVE is a more realistic representation, so corresponding equation for calculation of the volume of FVE was proposed (Goworek et al. 2000). The PALS method permits an estimation of the mean concentration of FVE or hole number density N - (Dlubek et al. 2003). In all the polymers, the N values are limited within relatively narrow range of $(2-8) \cdot 10^{20} \text{ cm}^{-3}$ at the glass transition temperature T_g (Dlubek et al. 2003; Yampolskii 2010). Computer modeling of polymers indicates that the use of FVEs dispersed in dense continuous matrix is only a convenient oversimplification. In reality the nanostructure of polymers is better approximated as a more or less continuous form of free volume, though the sizes of FVEs get within the size distribution of free volume according to molecular dynamics (Hofmann et al. 2003).

Free Volume Estimation

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical
Synthesis, Russian Academy of Sciences,
Moscow, Russia

Originally, *free volume* was interpreted (H. Fujita, M.H. Cohen and D. Turnbull, J.S. Vrentas and J.L. Duda) as an abstract parameter that fits the equation of *free volume model*. The methods for quantitative determination of free volume were proposed by S. Sugden and later by A. Bondi (1968). According to the latter, free volume V_f (cc/g) can be estimated as the difference: $V_f = V_{sp} - V_{occ}$, where the specific volume is defined as $V_{sp} = 1/\rho$ (ρ is the polymer density), while occupied volume V_{occ} can be found as $1.3 V_w$, where V_w is the *van der Waals volume* of the repeat unit of the polymer. The V_w value can be estimated from the increments tabulated for various groups (Van Krevelen and te Nijenhuis 2009). The factor 1.3 is taken from the packing density of molecular crystal at 0 K (accounting for inaccessible volume). Bondi's formula was criticized: the factor 1.3 might not be a universal constant, applicable in all cases; V_w of repeat units cannot be considered as the sum of increments of the groups that form

it. However, V_f value found using this formula is a simple and convenient measure of free volume in polymers (especially glassy) and it found a wide use. Often, it is more convenient to use a dimensionless value, *fractional free volume* FFV defined as V_f/V_{sp} . It is widely used in many correlations. In most polymers, FFV is in the range 0.1–0.25; however, there are examples where it reaches the value of 0.35.

Since the 1990s, several experimental methods (so-called probe methods) appeared and started to be used for the direct estimation of free volume in polymers (Yampolskii 2007). Among these methods (inverse gas chromatography, ^{129}Xe -NMR, and others), the most accepted and reliable one is the *positron annihilation lifetime spectroscopy* (PALS) (Dlubek 2008). It is based on the measurement of annihilation lifetimes of o-Ps (hydrogen-like atom formed by electron and positron): the longer its lifetime, the larger is the microcavity in the polymer where it resides and annihilates. The method permits estimation of discreet lifetimes or its distribution (hence, size distribution of microcavities). In conventional glassy and rubbery polymers, the radius of microcavity R (it is assumed that it has spherical geometry) is in the range 0.2–0.3 nm; however, in highly permeable polymers, it can be as large as 0.7 nm. In conventional polymers, o-Ps lifetime distribution and *free volume size distribution* is monomodal (Gauss-type distribution). In highly permeable polymers, it is, as a rule, bimodal with prevailing larger microcavities. By combining PALS and PVT data, it is possible to estimate the concentration of microcavities or hole number density N (Dlubek 2008). In all polymers, the N values are in the range 10^{20} – 10^{21} cm^{-3} . It is possible also to calculate PALS-based $\text{FFV} = N(4/3)\pi R^3$. Different probe methods give the radii of microcavities in rather good agreement (Yampolskii 2007).

Free Volume Model

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, Russia

The concept of free volume is extensively used in respect of various properties of condensed phases. Regarding nonporous polymeric membranes, it is quite useful in the description of diffusion phenomena. The model proposed by Cohen and Turnbull (1959) for transport in liquids and amorphous glasses considers a matrix consisting from hard molecules. It gives the following equation for the diffusion coefficient as a function of average free volume per molecule v_f : $D = A \exp(-\gamma v^*/v_f)$, where A is the constant, γ is the constant that takes into account possible overlapping of microcavities, and v^* is the minimum required volume of microcavity and often is considered as the size of the diffusing molecule. A modified equation was proposed later by Fujita (1961) where instead of v_f , the fractional free volume (FFV) was used:

$D = A_d R T \exp(-B_d/\text{FFV})$. It is accepted that the constants A_d and B_d depend on the nature (size) of the diffusants. These equations are valid only when the concentration of penetrants is small and they do not exert perturbation on polymer matrix (e.g., swelling). In transport of organic vapors, much more complicated equations were proposed and used (Vrentas et al. 1977; Petropoulos 1994). It is important that these equations include an activation term $\exp(-E_j/RT)$, where E_j is the energy needed for the diffusing molecule to jump into the next hole.

Free volume found using either of abovementioned models usually shows good

correlations with the diffusion coefficients of gases in polymers and often with the gas permeability coefficients. The concept of free volume was strongly enriched by the use of contemporary simulation methods (molecular dynamics, molecular mechanics, and Monte Carlo) and experimental probe techniques. However, in many cases (especially for highly permeable polymers), it is important to supplement the consideration with information on connectivity (openness) of free volume (Willmore et al. 2006).

Freundlich Isotherm

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

A Freundlich isotherm is a mathematical expression for the adsorption equilibrium between a fluid (liquid or gas) and a solid material. The Freundlich equation is an empirical expression representing the isothermal variation of adsorption of a liquid or gas onto the surface of a solid material, derived by Freundlich (1909) as an empirical relation.

For adsorption of a gas as the adsorbate to a solid adsorbent, the following equation represents a Freundlich isotherm:

$$\frac{x}{m} = kP^n \quad (1)$$

In this equation, x is the adsorbed quantity, m is the mass of the adsorbent, P is the partial pressure of the adsorbate in the gas, and k and n are empirical constants for each adsorbent-adsorbate pair at a given temperature.

For adsorption of a liquid, the relation between the adsorbed amount per gram of the solid at equilibrium Q (mg/g) and the concentration C in solution at the equilibrium (mg/l or $\mu\text{g/l}$) is given by the following equation:

$$Q = K.C^n \quad (2)$$

in which K and n are constants at a given temperature.

When the Freundlich equation is written in logarithmic form, a linear relation between $\log Q$ and $\log C$ is obtained:

$$\log Q = \log K + n \log C \quad (3)$$

Freundlich isotherms are often used to describe adsorption equilibria between a membrane and a feed solution. This is essential for the description of phenomena such as membrane fouling (Van der Bruggen et al. 2002) and breakthrough effects due to desorption (McCallum et al. 2008) in aqueous solutions. Desorption of adsorbed organic compounds to the permeate may result in negative apparent rejections when the concentration of the organic compound in the membrane phase is larger than the equilibrium permeate concentration given by the Freundlich isotherm. The permeate concentration during this unsteady-state filtration period is similar to breakthrough curves encountered in the description of adsorption columns. Kimura et al. (2003) demonstrated that adsorption of hydrophobic compounds, which can be described by the Freundlich equation, might lead to underestimation of the permeate concentration (or overestimation of rejection) due to saturation of the membrane and subsequent desorption. This is very important in the translation of experimental results to real scale applications. Thus, a fundamental understanding of adsorption is a prerequisite.

Adsorption equilibria using the Freundlich isotherm can also be used for membrane

characterization. Ge et al. (2006) demonstrated that the variation in membrane thickness and pore size can be predicted by studying Freundlich isotherms. They found that when the variations were larger, the time of total saturation is delayed, the loading capacity at the point of breakthrough decreases, the solute recovery efficiency and ligand utilization efficiency decrease, and the thickness of unused membrane increases.

The Freundlich isotherm is often used because of its simplicity and wide applicability. However, other isotherms can also be used to describe adsorption on membrane surfaces. The most commonly applied are the Langmuir isotherm and the BET equation. The Langmuir model was derived theoretically by Irving Langmuir in 1916 as a mathematical expression for monolayer adsorption onto a solid surface. Although this model has a theoretical basis, its application is limited to monolayers; in addition, the Langmuir model does not work well for rough surfaces, which is often the case for membranes. The Langmuir model was extended in 1938 by Stephen Brunauer, Paul Emmett, and Edward Teller, who developed a new theoretical model for multilayer adsorption that became known as the BET model (as an acronym for Brunauer-Emmett-Teller). Although more complex than the empirical Freundlich equation, it has the advantage of a strong fundamental basis, which goes beyond the simple approximation in the Freundlich model.

Fruit Juice Processing by Integrated Membrane Operations

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Fruit juice clarification, stabilization, depectinization, and concentration are typical steps where membrane processes such as microfiltration (MF), ultrafiltration (UF), reverse osmosis (RO), osmotic distillation (OD), and membrane distillation (MD) can be utilized as alternative technologies to the conventional transformation technologies. Particularly, MF and UF are valid approaches for the clarification of fruit juices as alternative to the use of fining agents, such as gelatin, diatomaceous earth, bentonite, and silica sol, which cause problems of environmental impact due to their disposal (Echavarria et al. 2011).

Clarified juices coming from MF or UF processes can be commercialized or submitted to a concentration process in order to obtain a product suitable for the preparation of juices and beverages.

RO, MD, and OD can be used as concentration techniques as alternative systems to thermal evaporation or cryoconcentration (Jiao et al. 2004).

Integrated membrane operations have been suggested for replacement of conventional juice processing unit operations for the clarification and concentration of different fruit juices as well as for the recovery of aroma compounds.

A typical example of integrated membrane system for the clarification and concentration of fruit juices is depicted in Fig. 1. The fresh juice is clarified by UF; the clarified juice is pre-concentrated by RO and then concentrated by OD. Pervaporation (PV) is used to recover aroma compounds from the fresh juice.

Technology, University of Tromsø, Navrik,
Norway
Energy Technology Research Group, Narvik
University College, Lodve Langes gt 2, Navrik,
Norway

Fuel cell is an energy conversion device which converts chemical energy of a fuel directly into electricity which can be used for light, heat, and shaft power. Therefore in principle fuel cell can replace heat engines for stationary power

generation and transport applications. The main types of fuel cells are as follows (Table 1):

Different types of fuel cell have been developed for different applications. For example, solid oxide fuel cell (SOFC) and molten carbonate fuel cell (MCFC) systems are used in stationary power generation or marine applications, whereas polymer electrolyte fuel cell (PEMFC) systems are chosen for automotive applications.

In the transport sector, the fuel cell has potential to replace internal combustion engine, and in the recent years, the use of fuel cell to power automobiles such as buses, motorcycles, train, boats, and airplanes has been demonstrated by various companies.

Fuel cell systems can generate power for distributed electricity (connected to grid) and grid-independent portable and small-scale generators for emergency and critical areas applications. Particularly for disaster areas and defense applications, fuel cell application is very attractive as fuel cell generates not only electricity, but it produces water also. Fuel cell plants prove to be very efficient for cogeneration, i.e., combined heat and power (CHP) for residential buildings or small communities as the waste heat can be utilized for

Fuel Cell Applications, Table 1 Fuel Cell Applications

Type	Electrolyte phase	Operating temperature	Electrolyte	Responsible ion
Molten carbonate fuel cell	Liquid electrolyte	500–650 °C	Molten carbonate	CO_3^{2-}
Phosphoric acid fuel cell		160–200 °C	Phosphoric acid	H^+
Alkaline fuel cell		60–220 °C	Liquid (KOH) immobilized	OH^-
Solid oxide fuel cell	Solid electrolyte	600–850 °C	Ceramic YSZ	O^{2-}
Polymer electrolyte fuel cell		–40–80 °C (120–180 °C HT)	Acid-doped solid polymer	H^+

heating. The fuel cell system for CHP varies between 2kWe for an individual house and 100kWe for small communities.

Portable fuel cell systems supply power in the same way as batteries and can also be used to charge batteries for small electrical devices.

Biofuel cells are at research stage, and several researchers are investigating their potential for generating electricity combined with applications such as waste treatment and metal recovery from waste streams.

Fuel Cell Components

Rajnish Kaur Calay

Institute for Building, Energy and Material Technology, University of Tromsø, Navrik, Norway

Energy Technology Research Group, Narvik University College, Lodve Langes gt 2, Navrik, Norway

All fuel cells essentially consist of two electrodes – an anode (negative side) and a cathode (positive side) – and an electrolyte to allow charges to move between the two sides of the fuel cell. Electrons are drawn from the anode to the cathode through an external circuit, producing direct current electricity. On both sides of the electrolyte and two electrodes (cathode, anode) are the catalyst layers. A catalyst lowers the activation energy to undergo a reaction and helps the reaction to take place at a faster rate. The fuel cell

type is defined based on the nature of the electrolyte. The six types are alkaline fuel cell (AFC), molten carbonate fuel cell (MCFC), phosphoric acid fuel cell (PAFC), proton exchange membrane or polymer electrolyte membrane (PEM) fuel cell, and solid oxide fuel cell (SOFC). The PEM and SOFC have solid electrolyte, while other three fuel cell types have liquid electrolyte. In a solid electrolyte fuel cell, for example, a PEMFC, the catalyst layer is spread either on the electrolyte (as in PEM or SOFC) or on the electrode. In addition to these basic components, other components are gas diffusion layer, electric connections, current collectors, separator plates, and seals. In PEM fuel cell bipolar plates made up of metal or conductive polymer (or carbon composites) have more than one function. Bipolar plates allow the transfer of electrons from the anode side of one cell to the cathode side of the adjacent cell, provide structural rigidity of the stack, distribute reactant gas to each cell within a stack, and distribute reactant gas within the cell in the stack through proprietary flow field topology (shape designs). In some cases, heat management can be integrated in BPP design which typically involves a thermally conductive medium being supplied through the stack to remove heat from the stack. Thermally conductive mediums typically can be air, de-ionized water, or a coolant with high specific heat capacity. Liquid electrolyte fuel cells will have electrodes immersed in the liquid electrolyte and often benefit from simplified design and also less expensive catalyst materials. As a result, liquid fuel cells, such as PAFC and MCFC, are well-established technologies and have been widely used for medium-scale

Fuel Cell Components, Table 1 Basic components of different fuel cells

Fuel cell type	Electrolyte	Electrolyte type	Catalyst
Alkaline	Solution of potassium hydroxide KOH	Liquid	Platinum
Molten carbonate	Sodium or magnesium carbonates (CO ₃)	Liquid	Nickel
Phosphoric acid	Phosphoric acid	Liquid	Platinum
Polymer electrolyte	Polymer electrolyte membrane	Solid	Platinum
Solid oxide	Ceramic compound of metal (like calcium or zirconium) oxides	Solid	Nickel

(<250 kW) stationary applications. Table 1 shown below gives an overview of each type of fuel cell, its electrolyte, and the primary catalyst used.

Fuel Cell Membrane

Antonino Salvatore Arico
CNR-ITAE Institute, Messina, Italy

Low-temperature fuel cells can be equipped with a proton or anion exchange membrane in alternative to liquid electrolytes (Aricò et al. 2001). The core of a polymer electrolyte fuel cell (PEMFC) is the ion exchange membrane. The electrodes (anode and cathode) are in intimate contact with the membrane faces. The membrane determines the fuel cell resistance and the fuel permeation rate, and it influences the reaction rate. It is well known that the use of non-noble metal catalysts is possible in the presence of alkaline electrolytes. Proton-conducting electrolytes have been preferred to alkaline electrolytes for several decades for practical reasons, e.g., to avoid carbonation.

The standard electrolyte membrane is usually a perfluorosulfonic acid membrane such as Nafion. Most of the electrolytes alternative to Nafion both proton conducting and alkaline type, e.g., hydrocarbon type, are significantly cheaper, and, in some cases, they are also characterized by smaller hydrogen and methanol crossover. However, lifetime characteristics similar to those shown by Nafion-type membranes in fuel cells have not yet been demonstrated for the alternative membranes. Concerning with the conductivity, only recently, membranes alternative to Nafion type have shown similar levels of performance. One critical aspect is related to the fact that the presence of water is a requirement of low-temperature PEMFCs and DMFCs for the occurrence of the electrochemical reactions and for the promotion of ionic conductivity (water-assisted conductivity mechanism). High ionic conductivities are often associated to the presence of large water uptake by the membrane, but this property often causes poor mechanical characteristics such as large swelling and relevant crossover (especially methanol). Phosphoric acid-doped polybenzimidazole membranes use a Grotthuss mechanism of proton transport and do not require water (Wang et al. 1995). These membranes operate at about 180–200 °C, whereas composite perfluorosulfonic acid membranes or sulfonated hydrocarbon membranes including inorganic fillers such as silica rely on the water-assisted mechanism, but they can operate up to 145 °C, under particular conditions (3 bar abs pressure), due to the enhanced water retention of the filler (Aricò et al. 2003).

Composite recast Nafion® membranes containing inorganic fillers have been employed in high-temperature (~150 °C) direct alcohol (Aricò et al. 1998) and H₂ air fuel cells (Watanabe et al. 1996). These composite membranes were originally developed for reduced humidification operation in polymer electrolyte fuel cells (Watanabe et al. 1996) due to the enhanced water retention inside the membrane by the effect of the inorganic filler (Aricò et al. 1998). A further advantage of composite membranes relies in the barrier effect given by the inorganic filler for methanol crossover (Ren et al. 1996).

Fuel production (pervaporation application)

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Fuel is any material that stores potential energy in a form that can be practicably released and used as heat energy. The conventional fuels refer to chemical fuels including fossil fuels and biofuels. Fossil fuels are hydrocarbons, primarily coal and petroleum (liquid petroleum or natural gas), formed from the fossilized remains. Biofuel can be broadly defined as solid, liquid, or gas fuel consisting of or derived from biomass.

Since the heightened concerns for cleaner air and more stringent environmental quality requirements for sulfur concentration in oil products, ultra-deep desulfurization from fuels, particularly from gasoline, has become a very important subject in petroleum refining industry. It is well known that sulfur removal from FCC gasoline can be achieved by catalytic hydrodesulfurization.

However, this hydrotreating process results in a significant reduction of octane number due to the saturation of olefins (Lin et al. 2009). Pervaporation has been given much more attention as a promising and feasible technology for desulfurization of gasoline since Grace Davison Company reported the pervaporation membrane-based S-brane process in 2002 (White et al. 2005). The sulfur components can be preferentially removed from the gasoline feed due to its higher affinity with and/or quicker diffusivity in the membrane. Pervaporation desulfurization demonstrates distinct advantages over conventional technologies such as low energy consumption, simple operation, and little reduction of octane number. The pervaporation membrane materials involved in desulfurization are mainly hydrophobic polymers including polyurethane (PU), polyurea/urethane (PUU), polyimide (PI), natural rubber and poly(styrene-co-butadiene) rubber, and polydimethylsiloxane (PDMS), as well as some hydrophilic polymers such as polyvinylpyrrolidone (PVP), cellulose triacetate (CTA), and polyethylene glycol (PEG) (Lin et al. 2009).

Among the variety of possible biofuels from the biorefinery, liquid transportation fuels in the form of bioethanol currently account for the vast majority of biofuels produced all over the world. A typical corn-to-ethanol production process consists of pretreatment of the starch to sugars with enzymes, fermentation of the sugars to ethanol with yeast, followed by distillation and dehydration processes of ethanol. Downstream from the fermentor is usually a dilute aqueous solution containing about 5–12 wt.% ethanol. Separation technologies such as pervaporation are applied for the subsequent ethanol/water separation. On the one hand, hydrophobic pervaporation membranes such as PDMS (Xiangli et al. 2008) and silicalite-1 zeolite membranes could be used for selective recovery of ethanol from fermentation broth. In addition, the fermentation process can be coupled with hydrophobic pervaporation membranes for in situ removal of the inhibitors (e.g., ethanol product and phenols) from the fermentation broth to realize the continuous fermentation. On the other hand, hydrophilic pervaporation membranes including PVA (Zhu et al. 2010) and NaA

zeolite membranes (Yang et al. 2012) could be used for dehydration of concentrated ethanol aqueous solution (usually containing 90–95 wt.% ethanol), obtaining the final bioethanol product.

- The usual surface modifications in the literature are the following: coating (Dickson et al. 1998), self-assembly (Luo et al. 2005), chemical treatment (Van der Bruggen 2009), plasma treatment (De Geyter et al. 2008), and surface graft polymerization (Belfer et al. 2004).
- The coating is a physical surface modification that can be obtained via one of the following mechanisms:
- Adsorption/adhesion – the functional layer is only physically fixed on the base material; the binding strength can be increased via multiple interactions between functional groups in the macromolecular layer and on the solid surface.
 - Interpenetration via mixing between the added functional polymer and the base polymer in an interphase.
 - Mechanical interpenetration (macroscopic entanglement) of an added polymer layer and the pore structure of a membrane.

The main limitation of this method is that it does not allow to prepare membranes with stable surfaces because the new materials on the membrane surface run away easily.

Self-assembly technique permits to obtain supramolecular systems. It entails self-assembly monolayers (SAMs), in which it has the adsorption of an active surfactant on a solid surface and layer-by-layer (LBL) assembly in which the assembly is obtained by means of alternative adsorption of linear polycations and polyanions. The only condition for the use of the self-assembly method is that the base membrane must be able to adsorb the first polyelectrolyte layer by means of ionic bonds.

The chemical treatment permits to obtain membrane surface modification with functional groups rather stable. The modified membrane retains the original mechanical properties, while the interfacial properties are changed. The chemical modification is obtained using a chemical reaction such as oxidation, substitution, addition, and hydrolysis.

The plasma treatment permits to obtain membrane surface with different properties changing

Fully Fluorinated Polymers

► Amorphous Perfluoropolymers

Functionalized Membrane

Teresa Poerio

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The functionalized membranes are membranes modified with appropriate functional groups that introduce new membrane properties, affinity or catalytic, for improving the selectivity or creating an entirely novel separation function (Ulbricht 2006).

parameter. Plasma gases are CF_4 , Ar, H_2 , He, Ne, N_2 , O_2 , and CO_2 , and the ionized gas can attack the C–C, C–H, and C–S bonds, excluding the aromatic C–C and C–H bonds. Surface modification with CO_2 plasma, generally, allows to obtain surface oxidation and the formation of hydrophilic surface; N_2 plasma makes amine, amide, imine, and nitrile functional groups on the membrane surface; and O_2 plasma leads to incorporation of oxygen containing functional groups such as hydroxyl, carbonyl, and carboxyl groups. Instead, to improve hydrophobic property of the membrane surface, high degree of fluorinated compounds such as SF_6 , CF_4 , and C_2F_6 are used as plasma gases.

Surface grafting is a chemical modification method. Compared with the physical methods such as coating, the covalent bond between the polymer chain and the membrane surface avoids the desorption phenomena maintaining the chemical stability of modified surface for long term. The grafting method is generally divided in two classes *grafting to* and *grafting from* based on different strategies of membrane functionalization. In the *grafting to* strategy, the polymer containing the reactive groups at the end or side chains is covalently coupled to surfaces, while in the *grafting from* strategy, an initiation, due to

active species on the membrane surface, permits the polymerization of monomer from the surface.

According to the different methods used for the surface activation, this technique is classified in chemical, radiation, photochemical, and plasma-induced grafting.

Galacto-oligosaccharide Membrane Reactor

Chiranjib Bhattacharjee¹ and Dwaipayan Sen²

¹Department of Chemical Engineering, Jadavpur University, Kolkata, West Bengal, India

²Department of Chemical Engineering, Heritage Institute of Technology, Kolkata, West Bengal, India

One of the preliminary issues with galacto-oligosaccharide (GOS) synthesis in batch reactor is the retention of monosaccharides, glucose, and galactose, within the reaction medium that hinders the transgalactosylation (Chen et al. 2003) reaction pathway through competitive inhibition of enzyme β -galactosidase. Hence, the removal of these monosaccharides from the reaction medium reduces the possibilities of enzyme inhibition and, thereby, increases the yield of GOS (Sen et al. 2011). In accordance to do so, presently continuous membrane separation process following the reaction is one of the upcoming strategies that are being introduced in the process (Sen et al. 2011; Das et al. 2011). As a whole the technology has been referred as “enzymatic membrane reactor” (Das et al. 2011). One of typical approaches in enzymatic membrane reactor is immobilization of the enzyme over the membrane, as shown in Fig. 1, where the substrate comes in contact with the membrane and the

product will be formed subsequently. The concept of such immobilization was taking place in 1978 (Chibata 1978). The process of immobilization suggests several techniques attributing to adsorption/covalent linking of the biocatalyst on some inert solid support, encapsulation within some semipermeable matrix, or insertion of the biocatalyst within the matrix network (Rios et al. 2004). Snamprogetti S.p.A. (Italy) and Sumitomo Chemical (Japan) are some of the companies that are using enzyme immobilization technique to produce GOS from lactose (Grosová et al. 2008). Snamprogetti S.p.A. used *K. lactis* β -galactosidase entrapped in cellulose triacetate fibers by fiber wet spinning, while Sumitomo Chemical has developed high-purity immobilized β -galactosidase from *A. oryzae* covalently bounded to macroporous amphoteric ion-exchange resin of phenol formaldehyde polymer. The simplest form of enzymatic membrane reactor as described by Czermaka et al. (2004) is where the reaction was carried out in a CSTR followed by the separation of enzyme using 50 kDa molecular weight cut-off (MWCO) membrane. This ensures the separation and, thus, reutilization of enzyme during enzymatic hydrolysis of lactose. However, the criticality here is, as said before, the retention of monosaccharides within the reaction mixture might hinder the process by product inhibition even though with the subsequent membrane separation. Therefore, the researchers became concern to develop a reactor,

Galacto-oligosaccharide Membrane Reactor, Fig. 1 Different forms of enzyme immobilization

Galacto-oligosaccharide Membrane Reactor, Fig. 2 Enzyme immobilization on membrane

where simultaneous production and separation will be carried out. In view of this, Sen et al. (2012) had suggested a module that will simultaneously behaves as a production and purification unit for monosaccharides. According to the membrane reactor, enzyme β -galactosidase (from *B. circulans*) was immobilized over a 0.3 kDa nanofiltration thin-film composite polyamide membrane with an immobilization yield of 83 %. According to the protocol elaborated, the membrane surface was primarily hydrolyzed to generate free amine groups that are required to form a covalent bond with the glutaraldehyde with subsequent covalent linking with the polyethylenimine and enzyme (Fig. 2). According to them, it was found that with the membrane reactor, the GOS yield becomes almost double compared to GOS yield in batch reactor. Moreover, it has been reported elsewhere that water-soluble enzyme on bind with membrane potentially increases the enzyme activity depending on the membrane organization and topology of the binding (Sánchez et al. 2013). However, the performance of such enzymatic membrane reactor depends on the stability of the enzyme protein that might undergo some conformational changes because of unfolding of the protein or in other word denaturation of the protein (Iyer and Ananthanarayan 2008). With immobilization on

inert support, like membrane, possibility of such changes could be restricted with enhanced enzyme stabilization (Mateo et al. 2007). Furthermore, to reduce the possible sugar fouling of membrane reactor, Sen et al. (2012) suggested one indigenously fabricated module called rotating disk membrane bioreactor.

Galacto-oligosaccharide Production by Membrane Operations

Chiranjib Bhattacharjee¹ and Dwaipayan Sen²

¹Department of Chemical Engineering, Jadavpur University, Kolkata, West Bengal, India

²Department of Chemical Engineering, Heritage Institute of Technology, Kolkata, West Bengal, India

Membrane separation process is one of the mostly coveted applications in different segments of industries, especially, in food engineering and effluent treatment sectors. One of the substantial advantages that attributes to the membrane separation process is the separation of the macromolecules (with respect to the membrane) without much operational complexity. This ensures the reusability and high yield of the separated components as retentate. However, membrane separation process has some primal intricacies that sometimes constraint the application of the process, especially, in food processing industries as prominent technology. One of such complexities attribute to primarily membrane fouling (Fig. 1) that reduces the performance as well as the reusability of the membrane. Polysaccharides' fouling of the membrane is such a significant contributor

Galacto-oligosaccharide Production by Membrane Operations, Fig. 1 Fouling of membrane

to the foulant genre that might reduce the performance of the separation process (Metzger et al. 2007). Separation of galacto-oligosaccharides (GOS) from the reaction medium comprising of sugars and other saccharides using membrane separation technique could be one of the tempting issues in recent pasts that has been explored by food scientists. During membrane separation process, the primary objective that has to be decided by the user is the proper selection of membrane molecular weight cutoff (MWCO) and the membrane material itself that has low vulnerability toward the carbohydrate adsorption on the membrane. The molecular weight of GOS varies from di to penta units of monosaccharides (340–828 Da). However, formation of more than tri could be sometimes trivial because of the steric hindrance that resists attaching the mono-sugar unit with the galactosyl moiety (Chen et al. 2002). Hence, the nanofiltration with 300 Da membrane could be a better cutoff in separating GOS from other sugars present in the reaction mixture (Sen et al. 2011). Moreover, the membrane material is one of the key issues that control the yield of GOS. Sen et al. (2011) studied that polyethersulfone (PES) and cellulose triacetate (CTA) membrane could interact with the monosaccharides produced during enzymatic reaction and results an inhibition of the enzyme restricting the production of GOS. Aforesaid fouling of the membrane because of sugars and polysaccharides leads to an implementation of diafiltration, where the reaction mixture is continuously diluted with a volume of water (either in batch (Fikar et al. 2010) or continuous process) depending on the volume concentration factor (VCF) (given by the ratio of the feed volume and retentate volume after batch) maintained during the diafiltration. Grandison et al. (2002) studied the purification of produced GOS with two different nanofiltration membrane

modules, dead-end and cross-flow, in diafiltration mode and concluded cross-flow nanofiltration yields more purified GOS. In addition, they had compared their results with different sets of membrane, where they concluded thin-film composite membrane performs better than cellulose triacetate membrane in the purification of GOS. One of the reasons that attributes to an enhanced purification in cross-flow system is the sweeping action across the membrane, which removes the fouling layer of the deposited sugars on the membrane. In 2007, Mellal et al. had used multi-shaft rotating disk system in order to purify oligosaccharides to depict the applicability of high-sheared membrane modules. Das et al. (2011) had shown that nanofiltration with rotating disk membrane module, another high-sheared membrane module, will create enough turbulence over the membrane enough to disrupt the concentration polarization and yield purified GOS. Therefore, purification of GOS is one of the prime concerns that can be done with a convenient membrane separation scheme attributing to some mechanically modified low fouling devices.

Galacto-oligosaccharides

Chiranjib Bhattacharjee¹ and Dwaipayan Sen²

¹Department of Chemical Engineering, Jadavpur University, Kolkata, West Bengal, India

²Department of Chemical Engineering, Heritage Institute of Technology, Kolkata, West Bengal, India

Galacto-oligosaccharides (GOS), one of the potential prebiotic carbohydrates that are commonly produced from lactose using enzymatic hydrolysis, is basically composed of oligo-galactose with some lactose and glucose (Niittynen et al. 2007). It is produced by a hydrolytic action of β -galactosidase (EC 3.2.1.23) on lactose through transgalactosylation (Chen et al. 2003) reaction, and depending on the source of the enzyme, it comprises of different synthetic by-products' mixture. A typical application in the utilization of GOS is its medicinal usage as prebiotic food-based ingredient that aims to enhance the growth as well as metabolic activity of potentially health-promoting indigenous bacteria such as bifidobacteria and lactic acid bacteria (Depient et al. 2008). GOS can't be hydrolyzed in the small intestine attributed as an indigestible component within the intestine as lactose for lactose-intolerant person. However, intestinal bacteria such as *Bifidobacterium* or *Lactobacillus* species can ferment them to a production of short-chain fatty acids' salt acetate (metabolized by muscle), propionate (metabolized by the liver), and butyrate (metabolized by the colonic epithelium) (Rodriguez-Colinas et al. 2013). GOS is primarily composed of di-, tri-, tetra-, and pentasaccharides with galactose as the monomeric unit (Chen et al. 2003). Figure 1a–c is showing the GOS structures of different polysaccharides' units.

Galacto-oligosaccharides, Fig. 1 Different forms of GOS: (a) di-GOS with galactose-galactose (1 $\rightarrow$ 6) linkage, (b) galactose-galactose (1 $\rightarrow$ 4), (c) galactose-galactose-galactose (1 $\rightarrow$ 4;1 $\rightarrow$ 4) linkage

Production of GOS primarily depends on pH, substrate (lactose), and temperature of the enzymatic medium. However, as aforesaid, source of enzyme will be an obvious reason in the production of GOS yield as well as the condition of other parameters. As, for example, β -galactosidase derived from *Aspergillus oryzae* has GOS yield of 52 % with lactose concentration of 500 g/L, pH 4.5, and temperature 40 °C (Gosling et al. 2010), while in the enzyme obtained from *Kluyveromyces lactis* with 400 g/L lactose concentration, 7 pH, and 40 °C temperature, the yield was only 24.2 % (w/w) (Gosling et al. 2010). Other reason that has an effect on the productivity of GOS is the enzyme inhibition because of the produced monosaccharides, glucose, and galactose, also termed as product inhibition. Figure 2 shows the enzymatic reaction to produce GOS from lactose. However, the inhibition differs on the source of enzyme. It had been seen that β -galactosidase extracted from *Kluyveromyces lactis* is more prone to galactose inhibition compared to glucose (Chockchaisawasdee et al. 2005). Galactose inhibition takes place in a competitive way (Gosling et al. 2010), while glucose inhibits in both competitive and uncompetitive way (Gosling et al. 2010). One of the critically acclaimed GOS products that is obtained in the market with substantial demand is Vivinal GOS syrup. The reason behind its syrupy form is its low solubility in water and is practically insoluble in ethanol as GOS is a mixture of different

Galacto-oligosaccharides, Fig. 2 Reaction schematics for GOS production from lactose with enzymatic route

carbohydrate polymers having different molecular weight with differential solubility. It had been seen that after producing GOS from lactose through enzymatic route, it can be separated out from the mixture of unreacted lactose, glucose, and galactose with 90 % (v/v) ethanol addition at 40 °C temperature (Sen et al. 2011).

Gas Diffusion Electrode (GDE)

Rajnish Kaur Calay
Institute for Building, Energy and Material
Technology, University of Tromsø, Narvik,
Norway
Energy Technology Research Group, Narvik
University College, Lodve Langes gt 2, Narvik,
Norway

The membrane electrode assembly is an assembly of an electrolyte and a catalyst layer either side of the electrolyte which is then hot pressed between two gas diffusion layers to form a single component. Each side of the membrane then forms an electrode, often called a gas diffusion electrode (GDE) which is a combination of the catalyst layer and the gas diffusion layer.

In the early days, sintered electrodes were used which were thick and quite heavy, but since 1970, bonding methods are employed to produce

electrodes with polytetrafluoroethylene (PTFE) materials. Electrodes made up of PTFEs are stable and have hydrophilic and hydrophobic properties which are important for providing required conductivity for electron transport and for removal of produced water. For acidic electrolytes such as the PEM, the principle catalyst used is platinum. An important feature for MEA preparation and manufacture is to ensure that there is good integration between the three components, the electrolyte, catalyst layer, and gas diffusion layer. These components must be interconnected to form a triphase point (TPP) which is critical for electrochemical reactions to take place and subsequently the performance of the fuel cell. The electrolyte and the Pt catalyst must be in contact to allow the transfer of the mobile ion to/from the reaction surface. The Pt catalyst must also have good contact with the GDL which will allow the transfer of electrons to and from the reaction site. Finally, the porous GDL must allow excellent diffusion of the reactant species to the reaction site while it facilitates product species away from the site. Careful optimization of the GDE is therefore essential as it is directly linked to the performance of the fuel cell and also the utilization of the Pt catalyst as the Pt catalyst that does not fulfill the triphase point criteria will not participate in electrochemical reactions.

Gas Diffusion Layer (GDL)

Rajnish Kaur Calay
Institute for Building, Energy and Material
Technology, University of Tromsø, Narvik,
Norway
Energy Technology Research Group, Narvik
University College, Lodve Langes gt 2, Narvik,
Norway

The GDL is important part of polymer electrolyte membrane PEM and direct methanol DM fuel cell. There are two gas diffusion layers

(cathode and anode sides) which as the name suggests diffuse reactant gases to the catalyst layer (of the electrolyte membrane). Other main functions include removing excess water and heat away from the catalyst layer for the smooth operation and preventing flooding. GDL is capable of retaining some water to ensure good conductivity throughout the membrane. It provides mechanical strength and support to the catalyst and membrane. GDL is electrically conductive; it also provides pathway for current collection. Thus, the main requirements of GDL are permeability of gases and water, conductivity, and mechanical strength. Due to these requirements, GDL is most commonly made up of carbon fiber-based products, i.e., cloth and carbon paper. As carbon cloth is thicker than carbon paper, it has certain advantages compared to carbon paper. Carbon cloth is made by weaving carbon fibers and therefore more flexible and stronger than carbon paper-based GDL layers. New generation GDL material combining the benefits of carbon cloth and paper is also being investigated by some researchers.

Due to different considerations for a GDL, many factors such as type of carbon used, pore formation, and thickness play an important role in the fabrication of GDL for a particular application. In most cases GDL consists of two layers: macroporous diffusion medium (DM) and microporous layer (MPL) typically 200–400 μm thick. DM has pore size ranging from 10 to 30 μm , and MPL has pore size of 0.05–5 μm and is purposely made hydrophobic by treating with small amount of Teflon or PTFE (5–10 wt.%). The small pore size creates a capillary pressure gradient across the membrane for effective removal of water away from the reaction sites.

Gas Permeability

► Permeability

Gas Permeance

► Permeance

Gas Permeation Unit (GPU)

May-Britt Hägg

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, Norway

The intrinsic permeation property of a gas through a membrane is characterized by the *permeability coefficient* P of a gas A, P_A . *Barrer* was early introduced as a practical unit for this property and made it easy to compare the suitability of materials to be used for membrane gas separation. *Barrer* is also defined below.

Permeance is directly related to the thickness, l , of the membrane and as such defined as pressure-normalized steady-state flux, P/l . The permeance will characterize the gas transport through the membrane. Permeance is an important parameter when comparing the separation suitability of membranes for mixed gases. A practical unit often used is *GPU* (*gas permeation unit*) (see below).

Permeability:

$$\begin{aligned} 1 \text{ Barrer} &= 10^{-10} \text{ cm}^3(\text{STP}) \text{ cm cm}^{-2} \text{ s}^{-1} \text{ cm Hg}^{-1} \\ &= 1.33 \times 10^{14} \text{ m}^3(\text{STP}) \text{ m m}^{-2} \text{ s}^{-1} \text{ kPa}^{-1} \\ &= 2.99 \times 10^{15} \text{ kmol m m}^{-2} \text{ s}^{-1} \text{ kPa}^{-1} \end{aligned}$$

Permeance:

$$\begin{aligned} 1 \text{ GPU} &= 10^{-6} \text{ cm}^3(\text{STP}) \text{ cm}^{-2} \text{ s}^{-1} \text{ cm Hg}^{-1} \\ &= 7.6 \times 10^{-9} \text{ m}^3(\text{STP}) \text{ m}^{-2} \text{ s}^{-1} \text{ kPa}^{-1} \\ &= 3.35 \times 10^{-3} \text{ kmol m}^{-2} \text{ s}^{-1} \text{ kPa}^{-1} \end{aligned}$$

(For conversions on membrane key parameters, please refer to: Table according to Journal of Membrane Science.)

Gas Permeation: Permeability, Permeance, and Separation Factor

May-Britt Hägg

Department of Chemical Engineering, Norwegian
University of Science and Technology,
Trondheim, Norway

General

Detailed information on the topic of gas separation with membranes can be found in numerous textbooks and chapters in membrane handbooks – only four book references are mentioned here: *Basic Principles of Membrane Technology* (Mulder 1996), *Materials Science of Membranes for Gas and Vapor Separation* (Yampolskii et al. 2006), *Handbook of Membrane Separations* (Pabby et al. 2015), and *Membrane Technology and Applications* (Baker 2012).

The use of membranes for gas applications dates back to the 1980s when the first commercial application was made economically feasible by the work of Henis and Tripodi (1980), for hydrogen recovery from a gas stream at a petrochemical plant. The first membranes developed were usually polysulfone or cellulose acetate, while today's commercial gas membranes include various types of polymers, especially should be mentioned polyimides. The research internationally on membrane materials for gas applications is comprehensive; however, relatively few new materials have made it to commercial applications. The potential for the industrial use of membranes in gas separation and purification is huge. The technology is environmentally friendly and a great technology for process intensification. The commercial processes where membranes for gas separation are applied today are mainly H₂ from gas streams, O₂/N₂, CO₂/H₂, CH₄/CO₂ (natural gas and biogas), vapor/gas separations, dehydration of air, and vapor/vapor separations. The potential for other gas separations is many.

There are basically two main categories of membrane gas separation: the synthetic materials

(polymers) and the inorganic materials (carbon, ceramic, metal (palladium especially)). The gas separation will take place according to different transport mechanisms depending on the intrinsic membrane material properties and the physical properties of the gases.

Dense polymeric materials may be in their glassy or rubbery state depending on their glass temperature (T_g) and the operating conditions. Separation is basically according to solution-diffusion. In its glassy state, the diffusion of the gas component will be governing the selectivity between the gases, while in its rubbery state, the solution of the gas in the membrane material will be of major importance. As a rule of thumb, the selectivity will be high and permeation low in a glassy, dense membrane, while selectivity will be low and permeation high in a rubbery material. The properties of the gas will also be important for the gas separation: an inert gas (like H₂, N₂, also CH₄) has very low critical temperature and will not easily dissolve in the material. Hydrocarbons, however, and nonideal gases like CO₂ have relatively high critical temperatures and will easily dissolve in the material and hence also swell the membrane. This will naturally affect the separation, and the selectivity will go down. It is thus of major importance to evaluate the suitability of the material for the separation of the gas pair in question and also with respect to process conditions for the potential application. The basic equations for gas separation are

$$J_i = -D_{ij} \frac{dc_i}{dx} \quad (1)$$

where J_i is the flux of component i [mol/(m²s)], D_{ij} is the diffusion coefficient [m²/s], and dc_i/dx is the concentration gradient for component i over the length x [mol/(m³·m)] (Fick's law). This converts to

$$J_i = \frac{P_i}{l} (\Delta p_i) \text{ when considering gases} \quad (2)$$

where $P_i = D \cdot S$ is the permeability of i (D is diffusion $\times S$ solution) and P_i/l is the permeance

of i through the membrane, while Δp_i is the partial pressure driving force of component i .

The “ideal” separation factor, α^* (Eq. 3), may be expressed by the ratio of the pure gas permeabilities for the individual components i and j :

$$\alpha_{ij}^* = \frac{P_i}{P_j} \quad (3)$$

The separation factor for gases in mixture α_{ij} (Eq. 4) is expressed by the mole fractions of the components in the feed (x) and the permeate (y), respectively:

$$\alpha_{ij} = \frac{y_i / y_j}{x_i / x_j} \quad (4)$$

As a general rule, the driving force of membrane gas separation is the difference in partial pressures (concentrations) between feed and permeate side. It is however more correct to say that the driving force is the difference in chemical potential thereby including the effect of temperature. (An additional driving force may be an electric potential or a carrier effect for certain types of membranes.) New membrane materials may combine different transport mechanisms and thereby increase the flux and selectivities.

Transport through a dense polymer may be considered as an activated process which can be represented by an Arrhenius type of equation. This implies that temperature may have a large influence on the transport rate. Equations 5 and 6 express the temperature dependence of the diffusion coefficient and solubility coefficient in the Eq. $P = D \times S$:

$$D = D_0 \exp(-E_d/RT) \quad (5)$$

$$S = S_0 \exp(-DH_s/RT) \quad (6)$$

where E_d is the activation energy for diffusion, ΔH_s is the heat of solution, and D_0 and S_0 are temperature-independent constants.

Several ways are investigated in trying to increase the separation factor. New polymeric membrane materials may be functionalized to

promote the permeation of one of the components, or the membrane may be a mixed matrix, i.e., with (nano)particles dispersed in the polymeric phase. The functionalization will then add an extra driving force to the permeation, and an extra term will be added to Eq. 2, as shown in Eq. 7 below. The characteristic of facilitated or carrier-mediated transport is the occurrence of a reversible chemical reaction or complexation process in combination with a diffusion process. The total flux of a permeant A will thus be the sum of both the Fickian diffusion (Eq. 1) and the carrier-mediated diffusion as illustrated below. The driving force in both terms is here expressed as concentrations, c :

$$J_A = \frac{D_A}{l} (c_{A,0} - c_{A,l}) + \frac{D_{AC}}{l} (c_{AC,0} - c_{AC,l}) \quad (7)$$

where the first term on the right-hand side of the equation is the Fickian diffusion (D_A) and the second term represents the carrier-mediated diffusion (D_{AC}). l is the thickness of the membrane.

The other main gas separation mechanism is the molecular sieving. In this group, one typically has the carbon membranes and other inorganic membranes. Molecular sieving depends on the pore diameter compared to the molecular diameter and will usually take place when diameter, $d_p < 5 \text{ \AA}$. If the pore is larger, there is the possibility of selective surface flow ($5 \text{ \AA} < d_p < 12 \text{ \AA}$) where the critical temperature of the gases will influence the separation. Too large pores may give Knudsen diffusion ($d_p > 20 \text{ \AA}$) which is not wanted.

The need for optimized membrane separation properties for specific gas mixtures has kicked off an explosive development with respect to tailor-made polymeric membrane. The first goal for most membrane material development is to document performance in the economically interesting region as shown in now so well-known Robeson plot for polymeric membranes, having an upper-bound trade-off between gas permeability and selectivity (Robeson 2008) – shown here in Fig. 1. The gas separation will, however, depend

**Gas Permeation:
Permeability,
Permeance,
and Separation Factor,**

Fig. 1 Selectivity for the gas pair CO_2/CH_4 as function of CO_2 permeability and the Robeson plot (squares for CMS (carbon) membranes, solid circles for TR (thermally rearranged) polymers, triangles for FSC (fixed-site-carrier) membranes, and solid diamonds for PIMs) (Adapted from Robeson 2008)

both on efficient separation of the gases in mixture and the relevant process conditions and, last but not least, also durability of the material over time.

Membrane gas separation is complex and challenging, and for a full understanding of the topic, competence on material technology and processes is needed. The *four books* listed here are excellent references on the topic.

Gas Separation

Mariolino Carta

School of Chemistry, The University of Edinburgh, Edinburgh, Scotland, UK

Gas separation is a widely used technique in which the objective is the separation of one or more gases from a mixture. It is becoming crucial for several industrial processes such as the treatment of fumes from coal-fired plants, in particular, aiming for the removal of CO_2 to reduce the greenhouse effect. Growing interest is also given to other applications such as the separation and purification of commercially important gases such as H_2 , CH_4 , and O_2 from natural gas. The most common methods to perform gas separation are:

1. Separation with solvent/sorbents
2. Separation by cryogenic distillation
3. Separation with membranes

Separation with Solvent/Sorbents

The separation with solvent/sorbents is based on the affinity of the gas toward a specific sorbent such as zeolites, alumina, or activated carbon or a solvent, for instance, MEA (methanolamine). The most illustrative example of this technology is represented by the pressure swing adsorption (PSA) method. The separation occurs when the gas mixture comes in contact with the sorbent/solvent in a vessel which is then pressurized. The gas with the highest affinity for the adsorbent is “trapped,” whereas the others pass through the system. The regeneration of the vessel is carried out by returning it to atmospheric pressure or by increasing the temperature, with release of the “trapped” gas. The main advantage of this technique is the high purity of the separated gas; the disadvantage consists in the high energy required

for running the system, especially for the regeneration of the vessel (Fig. 1).

Separation by Cryogenic Distillation

Cryogenic distillation is based on the fact that in a mixture of gases, they all have different boiling points and they could be separated by increasing/decreasing the temperature and pressure of the system in which they are stored, so that they can be divided into their single components. The gas mixture is cooled down to a low temperature (typically $< -50\text{ }^{\circ}\text{C}$). Once in the liquid form, the components of the gas can be directed in a distillation column, and through a series of compression, cooling, and expansion steps, they can be distributed to different channels, depending on their boiling points (Fig. 2).

G

Gas Separation,
Fig. 1 Schematic representation of pressure swing adsorption method (PSA)

Gas Separation,
Fig. 2 Schematic representation of cryogenic distillation method

It is a widely used technique for streams that already have a high concentration of desired gas (typically >90 %), but it is not very appropriate for more dilute gas streams.

The main advantage of the cryogenic gas separation is that it enables direct production of liquid gas, which is often very useful for certain transport options, such as transport by ship.

A major disadvantage is connected with the high amount of energy required for the refrigeration especially for dilute gas streams.

Gas Separation, Fig. 3 Schematic representation of membranes for gas separation

Separation with Membranes

Separation of gases with membranes relies on the different affinities of one or more gases toward the membrane material, causing one gas to permeate faster (or slower) than others. It is one of the fastest growing field for gas separation techniques, especially due to the high variety of materials which the membrane could be composed of, including microporous organic polymers, zeolites, ceramic, and metal-containing materials (for a more in-depth reading, see Yampolskii and Freeman (Yampolskii et al. 2010)).

The gas mixture is directed into a vessel and put in contact to the membrane material which is at the interface with another vessel (Fig. 3). The mixture is allowed to diffuse into the second vessel under a pressure gradient which promotes the mass transport through the membrane separating the retentate (slower gas) from the permeate (faster gas).

The use of membranes for gas separation offers several benefits, probably the most valuable is the high cost efficiency (both for the mechanical simplicity of the system and for low-energy regeneration). In fact, they do not require thermal regeneration, a phase change, or active moving parts in their operation.

Gas Separation,

Fig. 4 An example of Robeson plot, in this case O_2/N_2 (Carta et al. 2013). The black line represents the 1991 (Robeson 1991) upper bound, whereas the red line is the current (2008) upper bound (Robeson 2008)

Probably the greatest limitation of membranes for gas separation is derived from their trade-off relationship between permeability and selectivity for a required gas component. This means that high permeable membranes have low selectivity, requiring several run for a good separation, and highly selective membranes have low permeability, meaning long operational times. This trade-off was well addressed by Robeson in two well-known articles (Robeson 1991, 2008) in which he studied the gas separation performance of several membrane-forming materials in terms of permeability of a particular species (P_A) and selectivity toward one component of a gas pair ($\alpha_{A/B} = P_A/P_B$), organizing the data in double logarithmic plots for a series of commercially selected important gas pairs such as H_2/CH_4 , H_2/CO_2 , and O_2/N_2 . He confirmed that highly selective membranes generally exhibit low permeability and vice versa. The most important outcome of this study is represented by the so-called Robeson upper bound, an empirical line which is drawn for every gas pair plot that is meant to define how good a material for gas separation is. In Fig. 4, there is a typical example (Carta et al. 2013) in which the red line represents the 2008 upper bound for the gas pair O_2/N_2 . Supposedly, if we plot the selectivity $\alpha_{A/B}$ versus permeability P_A for a new membrane and the data point fall close or go over the upper bound, it is widely accepted that the material has an excellent compromise between P (rate of separation) and α (goodness of separation).

Gas Separation by Membrane Operations

Mariolino Carta¹ and Paola Bernardo²

¹School of Chemistry, The University of Edinburgh, Edinburgh, Scotland, UK

²Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The separation of mixtures of gases and vapors is required in manufacturing processes across various industries. In the last years, membrane systems are gaining a larger acceptance in industry for gas separation and are recognized as a cost-efficient separation able to compete with consolidated processes such as pressure swing absorption and cryogenic distillation (Bernardo et al. 2009; Sanders et al. 2013). Membrane processes have several advantages over conventional separation techniques (e.g., distillation, extraction, absorption, and adsorption), including modularity and compactness, operational flexibility, and no need for energy-intensive phase changes or potentially expensive adsorbents and/or difficult to handle solvents. The features of membrane operations allow implementing the process intensification strategy in different production cycles. Their versatility represents a decisive factor to impose membrane processes in most gas separation fields.

The first membrane units were installed in ammonia plants for the separation of hydrogen from nitrogen more than 30 years ago. Today, the production of nitrogen from air is the largest application of membrane systems, owing to the demand for nitrogen to inert fuel tanks, also aboard aircrafts, and for blanketing chemical and liquefied gas shipments. Membrane systems are also applied to enrich oxygen for medical uses, for hydrogen recovery and purification in refineries, for air and gas dehydration, and for ratio adjustment of gas mixtures. Natural gas processing represents an important emerging application field (Baker and Lokhandwala 2008). The relatively low volume flow and the relatively high inlet carbon dioxide content are strong drivers for the

implementation of the membrane technology in the biogas upgrading that it is at a developing stage (Makaruk et al. 2010). The challenging olefin/paraffin separation, not yet commercial, is attracting a lot of interest from the scientific community (Rungta et al. 2013).

Membrane separation allows recovering and recycling valuable compounds, such as hydrogen and light hydrocarbons (ethylene, propylene, and LPG), present in different off-gas streams (Baker et al. 1998). Polymeric membranes, cheap and with an easy processability, are typically used in the commercially available membrane system for gas separation (Yampolskii 2012). Commercial modules employ composite membranes (Pinnau et al. 1988), mainly in the form of compact hollow fibers. These membranes typically operate the separation based on a solution-diffusion transport mechanism: sorption of the permeant into the membrane, permeation by diffusion through the membrane, and desorption at the low-pressure side of the membrane.

The experimentally observed upper bound, based on various polymeric membranes, was reported by Robeson in 1991 and then updated in 2008 (Robeson 1991, 2008), thanks to the efforts to improve the gas separation performance of ultrahigh free volume and perfluoropolymers.

Glassy polymers are chosen for their size-selective behavior (e.g., in O_2/N_2 or H_2 separations). However, when applied to mixtures and/or at high gas activities, these materials are prone to plasticization, which causes swelling of the polymer matrix and results in a higher permeability coupled with a loss of selectivity. Strategies to overcome plasticization include thermal curing and chemical cross-linking, which reduce the polymer free volume (Wind et al. 2002). The addition of nanofillers to a polymer matrix represents an interesting solution to overcome the trade-off of the polymeric membranes and the inherent brittleness issues of inorganic membranes (Goh et al. 2011).

Rubbery polymers, instead, present a solubility-controlled permeation and preferentially allow the permeation of large gas or vapor molecules in a gaseous mixture containing also smaller molecules (Grinevich et al. 2011). Their permeability, much higher than in conventional

glassy polymers, increases with the critical volume of the penetrant (Matteucci et al. 2006). These materials are applied to the separation of organic vapors from non-condensable gases, treating petrochemical vent and process streams to recover valuable feedstocks (Baker 1999).

An interesting new concept is the use of water-swollen thin film composite membranes for biogas purification, taking advantage of the large difference in solubility in water to become selective for CO_2 (Kárászová et al. 2012).

Facilitated transport membranes contain carrier agents that can react reversibly with the target gas component. Therefore, the reaction in the membrane creates another transport mechanism, in addition to the simple solution-diffusion mechanism (Huang et al. 2008). However, carrier poisoning and short life span of the polymeric membranes are typically reported (Rungta et al. 2013). Ionic liquids were considered as additives for facilitated transport membranes. Indeed, their negligible vapor pressure avoids solvent losses by evaporation, providing stability to the metallic cation dissolved inside, and acting as a medium for facilitated transport with mobile carrier (Fallanza et al. 2013). Ionic liquid gel membranes based on conventional polymers (Jansen et al. 2011) or on polymer ionic liquids (Bara et al. 2008) were proposed to increase the stability compared to supported liquid membranes.

The key for new applications of membranes in challenging and harsh environments (e.g., petrochemistry) is the development of new tough, high-performance materials. In the field of inorganic membranes, metal organic frameworks were recently considered for preparing membranes to be applied to the olefin/paraffin separation (Bux et al. 2011) or as additive to a polymer matrix (Bushell et al. 2013).

High free volume polymers have been investigated as gas separation membranes, combining their ease of processing and mechanical stability with the potential to surpass the polymeric upper bound for different gas pairs (Budd and McKeown 2010). Novel PIMs, characterized by a significant shape persistence, were developed, showing interesting performance for the O_2/N_2 separation (Carta et al. 2013).

Properly designed hybrid processes, combining a membrane system with a conventional one (e.g., PSA or absorption), represent technically and economically viable solutions, able to reduce energy consumption and total costs (Esteves and Mota 2007).

Gas Separation Membranes: High-Temperature Glass Joining and Sealing

Marijke Jacobs

Sustainable Materials Management, Flemish Institute for Technological Research – VITO, Mol, Belgium

Gas separation membranes such as ceramic mixed ionic-electronic conducting (MIEC) membranes are able to transport oxygen or protons through their crystal structure at high temperatures

(>700 °C) in the presence of a driving force (Sunarso et al. 2008). This can be accomplished by sealing the membrane to a ceramic (alumina, zirconia, or mullite) or metal tube. Since the membranes can have different geometries, such as disk or tubular, diverse seal positions are possible, which are illustrated in Fig. 1.

This seal must be gastight at the operating temperatures (700–1000 °C) of the membranes. However, MIEC membranes have a very high thermal expansion coefficient ($\text{CTE} > 20 \times 10^{-6}/\text{K}$) compared to the materials to which they are bonded (CTE of $8\text{--}15 \times 10^{-6}/\text{K}$). As such, at the operating temperatures of the membranes, there is a big thermal expansion mismatch between the materials, which can cause failure of the joint. Therefore, to achieve a gastight joint, there must be a good wettability of the seal on the membrane and the support, and the seal must have a suitable viscosity and coefficient of thermal expansion (CTE) in the required temperature range. Once a seal is obtained, it must be thermal, chemical, and mechanical stable during the operation of the membrane to maintain the gastight joint.

There are different types of sealing methods for joining ceramic gas separation membranes at high temperature: metal-based seals, compressive seals, and glass-based seals. Metal-based seals can be applied by active metal brazing or reactive (air) brazing, and they will form a compliant seal. However, noble metals (Au, Pt) are expensive, while seals obtained with braze alloys, mostly Ag or Cu based, can suffer from cracks and delamination due to the CTE mismatch. Compressive seals are formed by using a deformable material, typically mica based, under a compressive load. This load is

difficult to apply on the ceramic membranes, and the seals are generally of lower quality than other types of seals. The last group of seals, the glass-based ones, form rigidly bonded seals by forming chemical bonds with the other materials and providing a hermetic joint. Furthermore, the properties of the glass or glass-ceramic seal can be tailored by changing the composition of the glass, and they are less expensive than noble metals (Qi et al. 2001; Mahapatra and Lu 2010; Vivet et al. 2011). As such, glass-based seals are very promising for high-temperature sealing of membranes.

A glass seal can consist of different constituents such as a network former (SiO_2 or B_2O_3), a network modifier (Li_2O , Na_2O , K_2O , BaO , SrO , CaO , MgO), an intermediate (mostly Al_2O_3), and an additive (Fig. 2). The first two constituents will have the most influence on the CTE, the glass transition temperature T_g , and the softening temperature T_s of the glass. These are important characteristics since the CTE must match as much as possible with the joining materials, T_g must be below the operating temperature of the seal otherwise the seal becomes brittle, and T_s must be higher than the operating temperature to avoid excessive flow of the seal.

An example of a glass-ceramic composite seal which can be used for high-temperature sealing of ceramic membranes for gas separation is based on Pyrex 7740 (SiO_2 80.6 wt%, B_2O_3 13 wt%, Na_2O 4 wt%, Al_2O_3 2.3 wt%, and K_2O 0.1 wt%), membrane material powder, and NaAlO_2 or B_2O_3 (Qi et al. 2001). This glass-ceramic composite is able to form a gastight seal between ceramic membranes such as $\text{La}_{0.8}\text{Sr}_{0.2}\text{Co}_{0.6}\text{Fe}_{0.4}\text{O}_{3-\delta}$ and $\text{SrCe}_{0.95}\text{Tb}_{0.05}\text{O}_3$ and alumina or mullite in the temperature range of 600–950 °C.

Gas/Vapor Transport

Johannes Carolus Jansen¹ and Marek Lanč²

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²University of Chemistry and Technology Prague, Prague 6, Czech Republic

General Introduction

Transport of gases and vapors in membranes depends first of all on their micro- and macroscopic structure. There is a fundamental difference between dense membranes, where transport takes place through the material of the membrane

itself, and porous membranes, where the transport takes place through the open space of the pores in the membrane. In the latter, different transport modes exist, depending on the size of the pores and on the interaction of the gases and vapors with the membrane material and with themselves. The most representative examples of transport mechanisms are shown in Fig. 1.

- (A) In large pores, convective or viscous flow occurs. Such membranes find application as filters to remove particulate matter from gas and liquid streams, but they are not able to separate gases, which move as a homogeneous mixture through the pores.
- (B) If the average pore diameter is smaller than the mean free path between the molecules in the gas mixture at the given pressure, so-called Knudsen diffusion takes place (Knudsen 1909; Datta et al. 1992). In this case, the transport rate is inversely proportional to the square root of the molecular weight of the gas species and the selectivity is only a function of their molecular weight ratios.
- (C) For even smaller pores, where the size of the pores is in the range of the size of the gas molecules themselves, molecular sieving can occur. Molecules that are larger than the pore size are completely excluded, and only smaller molecules may diffuse through the pores of the membrane. Such membranes can have very high selectivities, in the case of very narrow pore size distributions. Typical examples are carbon membranes (Vu et al. 2001) or zeolite

Gas/Vapor Transport, Fig. 1 Schematic representation of different transport mechanisms in porous and dense membranes

membranes (Caro and Noack 2008; Rangnekar et al. 2015). Also dense polymer membranes, when they have a combination of very high free volume and high stiffness of the polymer chains, may exhibit behavior that comes close to molecular sieving (Carta et al. 2013).

- (D) In the case of strong interaction of the membrane material with the permeating species or in case of readily condensable species, the latter condenses on the pore wall. In this case, what is the most permeable species depends on various factors, including the molecular dimensions of the permeating species of the mixture and on the remaining aperture of the pores, as well as the mobility of the condensed species on the pore surface.
- (E) In the extreme situation of the previous, capillary condensation takes place and the whole pore is filled with the condensed liquid. The selectivity of these membranes for gas mixtures may be completely different from the ideal selectivity for single gases. Based on the Knudsen diffusion mechanism, small molecules would always be much more permeable

than larger molecules. However, if the larger molecules condense inside the pore, the condensed phase obstructs the permeation of smaller molecules. Thus, the mixed gas selectivity may be opposite to the ideal selectivity.

- (F) In dense membranes, the molecules move through the bulk of the membrane material itself, or more precisely through its free volume. The rest of this chapter will focus mostly on the transport in dense membranes because of their relevance for gas separation applications.

Gas/Vapor Transport in Dense Membranes

Fick's Law of Diffusion

The penetrant flow, J , through a nonporous membrane can be described by Fick's first law of diffusion (Fick 1855), derived analogically to Fourier's law for the description of heat transfer.

$$J_i = -D_i \frac{dc_i}{dx} \quad (1)$$

where D is the diffusion coefficient and dc/dx the concentration gradient. The concentration in nonstationary conditions depends not only on the position in the continuous phase but also on time. Assuming one-dimensional diffusion, the transport behavior can be described by Fick's second law of diffusion:

$$\frac{\partial c_i}{\partial t} = D_i \frac{\partial^2 c_i}{\partial x^2} \quad (2)$$

Both equations assume that the diffusion coefficient is independent on concentration, which is true at low penetrant activity. Figure 2 describes the gas concentration profile at different times, for a previously evacuated polymer membrane after single-sided and double-sided exposure to a gas, based on Eq. 2 (Crank 1975). These profiles correspond to those in a typical permeation and sorption experiment, respectively.

Gas/Vapor Transport, Fig. 2 Concentration profiles in a flat sheet membrane (100 μm) calculated by Eq. 2, for $D = 10^{-12} \text{ m}^2 \text{ s}^{-1}$ (Crank 1975) in the case of: (a) ideal time lag permeation experiment (Relative feed concentration = 1, permeate concentration = 0); (b) ideal

sorption experiment (Relative feed concentration = 1) Arrows represent the increasing time during the experiment. Dashed lines represent the concentration profile in time equal to permeation time lag (see below)

The Solution-Diffusion Mechanism

The transport of gases and vapors in dense polymer membranes is governed by the solution-diffusion model (Wijmans and Baker 1995, 2006). The driving force of this process in dense membranes is the partial pressure gradient of the permeating species across the membrane, or more correctly its chemical potential gradient. The process consists of three steps: first, the gas is absorbed by the membrane at the polymer/gas interface on the feed side, then it diffuses across the polymer bulk, and finally it desorbs from the membrane at the permeate side. The permeability coefficient, P , is the product of the diffusion coefficient, D , and the solubility coefficient, S :

$$P = D \cdot S \quad (3)$$

where S is defined as the ratio of the equilibrium gas concentration, C , and the gas pressure, p :

$$S = C/p \quad (4)$$

The selectivity $\alpha_{A/B}$ of two species A and B is defined as the ratio of the two individual permeability coefficients and this can be decomposed into a diffusion selectivity term and a solubility selectivity term:

$$\alpha_{A/B} = \frac{P_A}{P_B} = \frac{D_A}{D_B} \cdot \frac{S_A}{S_B} \quad (5)$$

In ideal systems, such as for the transport of light gases in rubbers, P , D , and S are constants, but this is rather an exception and in many cases D and S depend on the concentration of the permeating species in the membrane and thus on the gas pressure. Numerous correlations have been proposed, relating the gas and vapor transport properties of polymeric membranes to the molecular properties of the penetrating species and to the chemical and physical properties of the polymer matrix, and they can be found in an excellent review (Matteucci et al. 2006).

In phenomenological terms, the membrane productivity is expressed by means of its permeance, defined as an amount of permeate per unit membrane area, time, and driving force. A commonly used unit is the gas permeation unit, GPU:

$$\begin{aligned} 1 \text{ GPU} &= 10^{-6} \frac{\text{cm}^3_{\text{STP}}}{\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}} \\ &= 2.70 \cdot 10^{-9} \frac{\text{m}^3_{\text{STP}}}{\text{m}^2 \cdot \text{h} \cdot \text{bar}} \end{aligned} \quad (6)$$

The permeance is a property of the membrane and depends on its effective thickness. The permeability coefficient is an intrinsic property of the material. The most commonly used unit to describe the permeability coefficient is the Barrer:

$$1 \text{ Barrer} = 10^{-10} \frac{\text{cm}_{\text{STP}}^3 \cdot \text{cm}}{\text{cm}^2 \cdot \text{s} \cdot \text{cmHg}} \quad (7)$$

Diffusion is an activated process and solubility is a thermodynamic property. The temperature dependence of diffusivity and solubility can therefore be described by the following Arrhenius and van't Hoff relationships, respectively (Van Amerongen 1946; Costello and Koros 1992).

$$D = D_0 \cdot e^{-E_D/RT} \quad (8)$$

$$S = S_0 \cdot e^{-\Delta H_s/RT} \quad (9)$$

where ΔH_s is the enthalpy of sorption of the penetrant in the polymer, E_D activation energy of diffusion, and D_0 and S_0 are the preexponential factors.

Assuming solution-diffusion model (Eq. 3), temperature dependency of permeability is:

$$P = P_0 \cdot e^{-E_P/RT} \quad (10)$$

where P_0 is preexponential factor and E_P activation energy of permeation which is equal to:

$$E_P = \Delta H_s + E_D \quad (11)$$

As a temperature-activated process, diffusion usually accelerates with temperature. Dissolution of the gas can be considered as a two-step process of condensation of the gas phase, followed by mixing with the polymer matrix. For light gases, the solubility therefore increases with increasing temperature, because the negative enthalpy of condensation is negligible with respect to the positive enthalpy of mixing. On the other hand, enthalpy of sorption of more condensable gases and vapors is negative due to the high negative enthalpy of condensation and the solubility decreases with increasing temperature.

Temperature dependency of diffusivity is usually stronger than that of solubility, and therefore the permeability usually increases with increasing temperature (Ghosal and Freeman 1994).

Gas/Gas, Gas/Vapor, and Vapor/Vapor Separation

The most important industrial applications of gas and vapor separations vary from (A) gas/gas separations to (B) gas/vapor separations, where the membrane is in contact with highly condensable species. In the extreme case of pervaporation (C), the membrane is at one side in contact with a liquid phase and at the downstream side it is in contact with a gas phase. The type of separation process dictates the possible operation conditions and the choice of the membrane materials.

- (A) For simple gas/gas separations, for instance, O_2/N_2 separation from air for pure nitrogen production or for O_2 enrichment, in principle many membrane materials can be safely used (Baker and Low 2014). The choice depends mainly on the need to achieve a high separation factor at relatively low flux or if a high flux is needed and the separation factor is less important.
- (B) For gas/vapor separations, the transport properties of the different species vary widely. Often the vapor consists of readily condensable large molecules, which have a high solubility in combination with a low diffusion coefficient, in contrast to the light gas, with a lower solubility and a high diffusion coefficient. In this case, the species in the mixture are likely to influence each other, directly via competitive sorption in the limited free volume available and indirectly via plasticization of the polymer matrix by the condensable species. The same situation occurs in gas/gas separations, where one of the two gases readily condenses at higher pressure, for instance, CO_2 . Typical examples are volatile organic compounds (VOC) removal from air (Leemann et al. 1996), or CO_2 removal from natural gas (Adewole

et al. 2013) or biogas, air dehydration, etc. For such separations, it may be convenient to use rubbery membranes, which are less prone to plasticization and which are solubility selective rather than diffusivity selective.

- (C) Pervaporation is the extreme case of vapor/vapor separation, with condensed vapors (=liquid mixture) at the feed side of the membrane and gaseous species at the permeate side, either by application of a vacuum or by the use of a sweeping gas (Mulder and Smolders 1991). Pervaporation is particularly advantageous in the case of azeotropic liquid mixtures, where the membrane can break the azeotrope. Typical examples of practical separations are the dehydration of alcohol with hydrophilic membranes, ethanol recovery from hydroalcoholic solutions, or VOC removal from wastewater with hydrophobic membranes. In terms of the transport properties, these membranes are often strongly affected by the swelling of the polymer by the permeating species. An exception is the alcohol dehydration with glassy perfluoropolymer membranes (Scholes et al. 2015a, b). A further complication in pervaporation with respect to gas/vapor separation is the existence of the Schroder's paradox, according to which the membrane material often behaves differently in contact with a liquid phase or in contact with the saturated vapor phase (Vallieres et al. 2006). A curiosity is that pervaporation membranes can be porous and nonselective in the dry state and become dense and selective in contact with the feed mixture (Van Der Bruggen et al. 2004, 2006).

Methods for Analysis of the Transport Parameters in Membranes

Time Lag Method for Pure Gases

The most common way to determine the basic gas transport parameters is the so-called time lag method (Crank 1975), in which the membrane is

Gas/Vapor Transport, Fig. 3 Typical permeation curve for analysis of pure gas permeability by the time lag method, with indication of time lag Θ determined via the tangent method

fully evacuated inside a closed permeation cell, and after exposure of the membrane to the gas at the feed side, the pressure at the permeate side is recorded as a function of time. For ideal systems, the concentration profile in the early stage of the experiment takes the form of Fig. 2a and the resulting permeation curve takes the form of Fig. 3, which is described by the following equation (Jansen et al. 2011):

$$p_t = p_0 + (dp/dt)_0 \cdot t + \frac{RT \cdot A \cdot l}{V_P \cdot V_m} \cdot p_f \cdot S \left(\frac{D \cdot t}{l^2} - \frac{1}{6} - ser \right) \quad (12)$$

with

$$ser = \frac{2}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \exp \left(-\frac{D \cdot n^2 \cdot \pi^2 \cdot t}{l^2} \right)$$

in which p_t is the permeate pressure at time t and p_0 is the starting pressure, typically as close to zero as the vacuum pump allows. In a leak-proof instrument, the baseline slope $(dp/dt)_0$ is usually negligible for a defect-free and well-evacuated membrane. R is the universal gas constant, T the absolute temperature, A the exposed membrane area, V_P the permeate volume, V_m the molar volume of a gas at standard conditions (0 °C and 1 atm), p_f the feed pressure, and l the membrane

thickness. The permeability coefficient, P , is calculated in the regime of quasi steady state permeation, which is defined by the simplified Eq. 13, describing the tangent to the linear part of the permeation curve:

$$p_t = p_0 + (dp/dt)_0 \cdot t + \frac{RT \cdot A}{V_P \cdot V_m} \cdot \frac{p_f \cdot P}{l} (t - \Theta) \quad (13)$$

The last term is the so-called permeation time lag, Θ , which is usually determined from the intersection of the tangents before the onset of permeation and after reaching the quasi steady state:

$$\Theta = \frac{l^2}{6D} \quad (14)$$

For a membrane of known thickness, it allows the determination of the diffusion coefficient of the gas. The gas solubility coefficient, S , can then be obtained indirectly as the ratio of the permeability to the diffusion coefficient, using Eq. 3.

While the transport parameters P and D are usually obtained by using the tangents to the permeation curve, the permeation curve can also be fitted directly with Eq. 12, after expansion into a sufficient number of terms (Scheichl et al. 2005; Jansen et al. 2011). This yields the values of P , D , and S directly. An inaccurate fit in the case of a deviating curve shape is a direct indication of nonideal behavior. This happens, for instance, in the case of clustering or in the case of strong dual mode sorption (DMS) behavior.

Constant Pressure: Variable Volume Method

In this method, the pure feed gas or the feed gas mixture flows through the membrane cell in cross-flow mode and the permeate is either collected as such or it is transported by a sweeping gas to the gas analyzer. The total permeation rate can be determined directly, for instance, by a bubble flow meter or electronic flow meters, measuring the volumetric permeate flow rate, J^{Permeate} . The permeate flux, Q^{Permeate} , is the volumetric flow rate per unit area:

$$Q^{\text{Permeate}} = \frac{J^{\text{Permeate}}}{A} \quad (15)$$

When using a sweeping gas, the permeate flux can also be calculated from the known sweeping gas flow rate and the gas concentration in the permeate/sweeping gas mixture. The individual gas permeance, Π , of the i th species in a gas mixture is obtained as the ratio of its volumetric permeate flux, Q^{Permeate} , to the partial pressure difference between the feed and permeate sides:

$$\Pi_i = \frac{x_i^{\text{Permeate}} Q^{\text{Permeate}}}{x_i^{\text{Feed}} p^{\text{Feed}} - x_i^{\text{Permeate}} p^{\text{Permeate}}} \quad (16)$$

in which x_i is the volume fraction or mole fraction of the i th species, p^{Feed} and p^{Permeate} are the total feed and permeate pressures, respectively. The mixed gas selectivity of species A and B , $\alpha_{A/B}$, is then calculated as the ratio of their individual permeances:

$$\alpha_{A/B} = \frac{\Pi_A}{\Pi_B} \quad (17)$$

Sorption Analysis

Direct sorption analysis is the most reliable way to determine the solubility of the gas in the polymer matrix. Sorption can be determined volumetrically, gravimetrically, and with the pressure decay method (Keller and Staudt 2005), or by inverse gas chromatography (IGC) (Danner et al. 1998). Equilibrium sorption in polymers is one of the basic characteristics describing the interaction between a penetrant and a polymer. In all these methods, the polymer sample is placed inside the test cell and exposed to a given penetrant pressure. In gravimetric measurements, the mass uptake can be measured electromagnetically (Mamaliga et al. 2004), by a quartz crystal microbalance (QCM) (Mikkilineni et al. 1995) or McBain's quartz spiral balance (Friess et al. 2011; Vopička et al. 2013).

Since the sorption coefficient (solubility) is usually a function of pressure or activity, knowledge of the sorption isotherm shape is important. There are many different types of sorption isotherms (Rouquerolt et al. 1994) depending on

the polymer structure and the relative difference between penetrant/polymer and penetrant/penetrant interaction.

Sorption of light gases in rubbery polymers increases linearly with pressure according to Henry's law. On the other hand, vapor's sorption can be described by numerous equations such as Flory-Huggins theory (Flory 1953), Flory-Rehner (Flory and Rehner 1943a; Flory and Rehner Jr. 1943b; Izák et al. 2003), Koningsveld-Kleintjens equations (Koningsveld and Kleintjens 1971), or the ENSIC model (Favre et al. 1996).

In the case of dense glassy polymeric membranes, three models are the most often used. Permanent gases behave almost linearly, at low pressures following Henry's law. Alternatively, the dual-mode sorption model, Eq. 18, gives usually a satisfactory description of the behavior (Barrer et al. 1958). This model is a combination of Henry's law and the Langmuir sorption isotherm, assuming monolayer sorption at existing sorption sites.

$$C = C_D + C_H = k_d \cdot p + \frac{c_h \cdot p \cdot b}{1 + b \cdot p} \quad (18)$$

where C is the gas concentration in the polymer, C_D and C_H are the Henry and Langmuir concentration contributions, respectively, k_d is the linear sorption parameter, c_h is the monolayer capacity, and b is the affinity parameter, reflecting the interaction strength between polymer and penetrant.

In the case of vapor sorption in glassy polymers, the sorption curves often have a typical S-shape and the DMS model cannot be used. In such cases, the Guggenheim, Anderson, and de Boer (GAB) model (Guggenheim 1966) gives a better description:

$$v = \frac{v_m \cdot h \cdot a \cdot f}{(1 - f \cdot a)(1 - f \cdot a + h \cdot f \cdot a)} \quad (19)$$

where v is the mass of adsorbed vapor per mass of polymer adsorbent, v_m is the capacity of the first adsorption monolayer, h defines the ratio of the adsorption strength in the first and the subsequent layers, a is the vapor activity, and f is a constant defining the deviation of the saturated vapor

Gas/Vapor Transport, Fig. 4 Gravimetric sorption isotherm of CO_2 in Amine-PIM-1 (Mason et al. 2014), extrapolated with GAB and DMS models

pressure from a chosen reference pressure. For gases, the following form of the GAB model was proposed (Vopička and Friess 2014).

$$v = \frac{v_m \cdot h \cdot p^* \cdot p}{(p^* - p)(h \cdot p + p^* - p)} \quad (20)$$

where p^* is a pressure independent constant which has the meaning of a reference pressure. When p^* is equal to saturated vapor pressure, the model is equivalent to the BET model (Brunauer et al. 1938) (Fig. 4).

For samples with a well-defined geometry, sorption kinetics measurements allow the determination of the diffusion coefficient by equations based on Fick's second law (Crank 1975). The relative sorbed amount Q_t/Q_∞ in a flat film with thickness l is given as a function of time by the following equation:

$$\frac{Q_t}{Q_\infty} = 1 - \frac{8}{\pi^2} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^2} \cdot e^{-\frac{D \cdot (2n+1)^2 \cdot \pi^2 \cdot t}{l^2}} \quad (21)$$

The corresponding concentration-time profile in a flat membrane during a sorption experiment is shown schematically in Fig. 2b. Under real conditions, a finite time is needed to charge the gas in the sorption apparatus and a correction for the assumed step-pressure-increase is necessary

Gas/Vapor Transport, Fig. 5 Typical gravimetric sorption kinetics curve. CO₂ sorption fitted with the model proposed by Vopička (Vopička et al. 2009) in microporous Tröger's base polymer EA-TB-PIM (Carta et al. 2013) after MeOH treatment

(Vopička et al. 2009). An example of a typical sorption kinetics curve obtained with this model is shown in Fig. 5.

Modeling of Transport

With the increasing computational power of modern computers, modeling of structural (Heuchel et al. 2008) and transport properties of gases (Hofmann et al. 2000; Frentrop et al. 2015) and vapors (Giacinti Baschetti and De Angelis 2015) in polymeric membranes has gained a prominent position in membrane research. Especially in the description of the free volume distribution of membrane materials, computational methods offer a level of insight that no single experimental method can give. The transport can be studied at the atomistic level (Hofmann et al. 2000; Theodorou 2006), showing, for instance, the “hopping” mechanism of a gas molecule from one free volume element to the next, confirming the activated mechanism seen experimentally. Although there is often a large discrepancy between the calculated sorption and diffusion coefficients and the experimental values, the trends between different gas species are usually

reproduced well in the simulations (Macchione et al. 2007; Jansen et al. 2010). Whereas molecular dynamics simulations work fairly well for small molecules at low concentration, like in gas separation, models to analyze and predict the mass transport in pervaporation require different approaches (Lipnizki and Trägårdh 2001), such as the UNIQUAC model (Heintz and Stephan 1994).

Transport in Heterogeneous and Homogeneous Mixtures

The description of the transport in polymers with homogeneously or heterogeneously dispersed additives or in polymer blends is much more complex than that in neat polymers. Mixed matrix membranes are currently receiving much attention (Aroon and Ismail 2010; Rezakazemi et al. 2014) because they have the potential to combine the high permeability and selectivity of inorganic (e.g., zeolites (Miller et al. 2007)), carbonaceous (Vu et al. 2003), and organometallic filler particles (metal organic frameworks, MOFs (Bushell et al. 2013; Zornoza et al. 2013; Adatoz et al. 2015)) with the good mechanical properties of polymers. There is a large number of predictive models to describe the performance of MMMs (Vinh-Thang and Kaliaguine 2013). One of the simplest and most commonly used models to describe the transport in MMMs is the Maxwell model (Shimekit et al. 2011), valid for a low concentration of spherical particles dispersed in the continuous phase:

$$P_{eff} = \frac{P_d + 2P_c - 2\phi_d(P_d - P_c)}{P_d + 2P_c + 2\phi_d(P_d - P_c)} \quad (22)$$

where the P_{eff} is the effective permeability of the mixed matrix membrane, P_c and P_d represent the gas permeabilities in the continuous and dispersed phase, respectively, and ϕ_d is the volume fraction of the dispersed phase. Generally, the permeability of the gases through the dispersed phase depends on the overall void volume, its distribution in the filler particles, and on the channel size, which affect the free volume of the overall system.

More sophisticated models take into account also the particle shape of the dispersed phase (Cussler 1990). Such particles may have a pronounced effect in the case of high aspect ratios (Rodenas et al. 2014) due to the strong effect on the diffusion path length (Falla et al. 1996). Interestingly, also impermeable fumed silica (Merkel et al. 2002) or graphene (Althumayri et al. 2016) filler particles, with intrinsic barrier properties, can have a positive effect on the permeability of the membranes, when additional free volume is created at the polymer-particle interface.

When the dispersed phase is another polymer, in the case of immiscible polymer blends, the transport can be described by fundamentally the same equations as the mixed matrix materials (e.g., Eq. 22). Instead, for miscible polymer blends, the permeability, P_b , is reported to obey the following equation (Robeson 2010):

$$\ln P_b = \phi_1 \ln P_1 + \phi_2 \ln P_2 \quad (23)$$

in which ϕ_1 and ϕ_2 are the volume fractions of the two polymers, respectively, and P_1 and P_2 are their permeabilities. It shows a linear trend when the permeabilities are plotted on a logarithmic scale and deviates from linearity in the case of (partial) immiscibility of the two polymers (Jansen et al. 2013).

Overall Performance

Robeson Trade-Off Behavior

Although membrane separations may have many advantages compared to traditional separation processes such as distillation or pressure swing adsorption, a limitation is the trade-off behavior between selectivity and permeability. This trend was firstly discussed by Robeson in 1991, who suggested a linear so-called upper bound for many relevant gas pairs (Fig. 6) (Robeson 1991), which were subsequently updated and extended (Robeson et al. 1994; Robeson 2008). In 2015, a new upper bound was set for O_2/N_2 , H_2/N_2 , and H_2/CH_4 , based on mostly the development of polymers of intrinsic microporosity (Swaidan et al. 2015). Freeman discussed the basis of the

Gas/Vapor Transport, Fig. 6 O_2/N_2 1991 and 2008 upper bound curves for the selectivity versus permeability trade-off relation (Robeson 1991, 2008) with the latest upper bound suggested by Swaidan et al. (2015). The oval represents the approximate cloud of experimental data

upper bound (Freeman 1999) and concluded that a combination of high free volume and extreme rigidity of the polymer chains is needed to exceed the current upper bound (Robeson et al. 2009). This was confirmed by McKeown et al. with a novel polymer of intrinsic microporosity based on Troger's base and ethanoanthracene (Carta et al. 2013) or benzotriptycene units (Rose et al. 2015). Alentiev presented a similar approach for the trade-off in diffusion coefficient and diffusion selectivity (Alentiev and Yampolskii 2013).

Effect of Physical Aging on the Transport Properties

The global nonequilibrium state of glassy polymeric membranes tends to relax over time. This process, where no chemical changes occur, is called physical aging (Struik 1978) and affects different properties of a polymer. One of these is the free volume distribution, which, in turn, is reflected in the gas transport properties of the membrane. Physical aging therefore has a strong impact on the performance of amorphous glassy gas separation membranes (Pfromm 2006), and gas diffusion is a very sensitive method to probe

changes in the free volume of a polymer membrane (Jansen et al. 2009). Different aging mechanisms have been proposed. Harms claims that free volume elements diffuse towards the surface of the polymer (Harms et al. 2012). However, due to the very low expected diffusion coefficient of this process, it is significant only in the case of thin layers. McCaig et al. proposed that the aging consists of two distinct processes (McCaig and Paul 2000): (i) thickness independent lattice contraction and (ii) thickness dependent diffusion of free volume. Usually, the polymer chains pack more efficiently during physical aging and the polymer becomes denser, resulting in a decrease in permeability and an increase in selectivity. Many approaches have been used to overcome physical aging and to prepare time-stable material, such as crosslinking and addition of fillers. Lau et al. showed that addition of an ultraporous additive can prevent the effect of aging on the transport properties of super glassy polymer membranes (Lau et al. 2014).

Anomalous Transport

As already anticipated, Fick's first and second laws give a rather simplified representation of diffusion in polymers, which usually applies only to permanent gases at low pressures. In the majority of cases, the diffusion coefficient is not a constant, because of mutual interactions between the permeating species, giving rise to clustering (Jansen et al. 2011) and interaction between the polymer and the permeating species, "immobilizing" the latter (Mason et al. 2014) or plasticizing the polymer (Lo et al. 2010) and favoring diffusion. The solubility of gases and vapors in the polymer matrix is usually only constant at very low gas pressure or vapor activity. As a result, the simple expression for the solution diffusion model in Eq. 3 becomes concentration dependent:

$$P(c) = D(c) \cdot S(c) \quad (24)$$

This anomalous behavior becomes even more complex in the case of mixed gas or vapor permeation, where there may also exist a coupling effect between the different species in the mixture.

Synonyms

Gas–liquid exchangers using membrane as interface; Nondispersive gas–liquid contactor

History

Gas–liquid contactors are devices which are designed to promote mass transfer between a gas phase and a liquid phase, thanks to gas–liquid contact. Among the various types of existing contactors, e.g., valve trays, random or structured packing, demister, vacuum towers, etc., and membranes, one can clearly distinct two categories: firstly, contactors requiring a straight mixing between the gas and the liquid phases and, secondly, contactors where the direct physical contact between the two phases does not exist, i.e., a contactor which does not need dispersion of one phase into the other one to be efficient (Fig. 1).

Up to now, membrane contactors are the only example of the second category, i.e., systems which are simultaneously able to avoid phase mixing while promoting mass transfer. Obviously the higher the membrane permeability, the better is mass transfer efficacy. Currently, most of the industrial applications are using microporous membrane contactors (Liqui-Cell® 2014).

Like with other gas/liquid contactors, the mass transfer obtained by means of contactors can be

Gas–Liquid Membrane Contactor, Fig. 1 Schematic representation of a G/L membrane contactor

directed to carry out either separation and purification operations of a gas mixture by the selective removal of a given gas component or, conversely, absorption of gas (e.g., N_2 , O_2 , O_3 , etc.) in the liquid phase. The driving force is the gas partial pressure according to the Henry law: $p_i = Hx_i$ with p the partial pressure, x the concentration of gas at equilibrium, and H the Henry law coefficient. Note also that the driving force of the mass transfer can also be due to a chemical reaction between the gas species and the liquid phase.

Phenomenon

In the 1980s, Qi and Cussler (1985) achieved pioneering work devoted to the understanding of mass transfer in gas–liquid membrane contactors. Within this specific type of contactors, the membrane is primarily a physical barrier between a gas phase and a liquid phase. So to get an efficient device, a proper choice of membrane and operating conditions must be done to ensure a high level of mass transfer. For the membrane selection, it turned out that a microporous structure looked to be the best one to gather appropriate mechanical properties and high mass transfer coefficient. Most of the time, the liquid phase used is an aqueous phase; hence, it logically orientated the selection of membranes to hydrophobic rigid polymers, i.e., glassy or semicrystalline structures, like polypropylene (PP) (Fig. 2), polyvinyl difluoride (PVDF), or Teflon. Thus the aqueous phase cannot enter spontaneously the small pores ($\approx 0.1\text{--}1.10^{-6}$ m) of the membrane structure, as predicted by the Young–Laplace equation given below. Nevertheless, the main concern with a

Gas–Liquid Membrane Contactor, Fig. 2 Microporous polypropylene

microporous membrane contactor is to avoid pore wetting by the liquid phase, because pore wetting would induce a detrimental decrease of the overall mass transfer coefficient (Fig. 3a, b). In case of pore flooding, the mass transfer coefficient can drop by a factor 1,000–10,000.

Hence there is a breakthrough pressure to be respected; this limiting pressure (Δp) difference between the two phases can be calculated by the Young–Laplace equation (Kim and Harriott 1987):

$$\Delta p = -4\gamma_L \cdot \cos \theta / d_{\max} \quad (1)$$

with γ_L the surface tension of water, θ the contact angle, and $d_{\max}$ the diameter of the biggest micropores.

As a guide, using pure water ($\gamma_L = 72.8$ mN/m at 20 °C) and PP (with pore $d_{\max} = 1$ μm and $\theta = 115^\circ$), the breakthrough pressure is 1.23 bar. However in reality, the measured breakthrough pressure is often much lower due to the presence of impurities or organic solutes in the water; any alteration of the polymer surface properties can also lower this value. On the other hand, to avoid any gas bubbling in the liquid phase, a slight overpressure is usually applied at the membrane liquid interface.

Mass Transfer Theory

As one can expect, the mass transfer extent is closely related to the operating parameters, i.e.,

Gas-Liquid Membrane Contactor, Fig. 3 (a) In a nonwetted porous membrane, the membrane transport occurs in gas-filled pore. (b) In a wetted porous membrane, the membrane transport in liquid-filled pore is much slower

mainly gas partial pressure in each phase, temperature, gas and liquid flow rates, hydrodynamic conditions, and the specific transfer area. To achieve a given purification target, the mechanism of the gas/liquid transfer must be known and used to model the mass transfer and thus to predict adequate operating parameters.

The performance of the mass transfer can be related to the variation of gas composition either between the inlet and the outlet of the gas phase or between the inlet-dissolved gas and the outlet-dissolved gas of the liquid phase. For a fast reaction with a steady gas phase velocity, the same basic equations, which are used to predict transferring gas in conventional columns, also apply for membrane contactors as recalled below:

$$\frac{C_{Gout}}{C_{Gin}} = e^{-k \cdot a \cdot L / u_g} \quad (2)$$

where C_{Gout} and C_{Gin} are respectively the outlet and inlet gas concentrations, k is the overall mass transfer coefficient, L is length of the contactor, a is the contact area between the two phases, and u_g is the gas phase velocity.

Noting one can define the gas transfer efficiency $\eta = (C_{Gin} - C_{Gout}) / C_{Gin}$, thus one can write:

$$\frac{C_{Gout}}{C_{Gin}} = 1 - \eta = e^{-k \cdot a \cdot L / u_g} \quad (3)$$

It is worth noting that modeling the mass transfer properties of a membrane contactor is even easier than with conventional contactors because the

gas/liquid contact area is well known and remains constant whatever the gas or liquid flow rates.

As shown in Fig. 3, the overall mass transfer resistance is due to the successive resistances of the gas phase, of the membrane, and of the liquid phase. Clearly the analogy can be made with electrical resistances, and the reciprocal of the overall mass transfer coefficient (k_{ov}) can be written as the sum of the individual mass transfer coefficients:

$$1/k_{ov} = 1/k_{gas} + 1/k_{membrane} + H/k_{liquid} \quad (4)$$

H being the Henry law constant between the gas and liquid phases.

Pros and Cons

Compared to conventional gas/liquid contactors (tower, packed columns, mixer settler), membrane contactors are known to avoid a number of drawbacks due to phase dispersion such as solvent loss, foaming, unknown specified area, and column flooding. It is worth also to underline that as polymer is the core of membrane contactors, one can get a strong reduction in weight of the equipment compared to conventional ones. At last one can note as well that a membrane contactor can be installed horizontally or vertically without problems and that its efficiency is not dependent of roll and pitch marine.

Note that liquid-liquid extraction can also be achieved using membrane contactors, hence avoiding any hazard of emulsion formation.

All these advantages are linked to the mixing nondispersive feature of a membrane contactor.

On the other side, drawbacks can come from the facts that the pores of a membrane do not have the same size, that pore fouling can occur and block the transfer, and that the hydrophobic properties of the surface can be altered inducing a dramatic decrease of the breakthrough pressure.

Intensification Potential of Mass Transfer

As with any membrane modules, the membrane contactors can be prepared with different geometries, going from plate and frame modules, spiral modules, or hollow fiber modules. The last type has received the most attention because it allows the creation of very large interfacial areas, up to $10,000 \text{ m}^2/\text{m}^3$ that is up to 20-fold the interfacial area of a structured packed column (Gabelman and Hwang 1999; http://docnum.univ-lorraine.fr/public/INPL/2011_NGUYEN_P_T.pdf6). Thus the factor **k.a.**, which is one of the key parameters predicting the mass transfer efficiency (Eq. 3), indicates clearly that for a constant value of **k**, a strong intensification of the transfer can be reached with membrane contactors.

This high value of area will be obtained with fibers having very low inner diameter, typically in the 50–100 μm range. Hence, a limit of the transfer with membrane contactor can now be foreseen: the increase of the specific area shall correspond to an increase of the pressure drop in the fibers of smaller diameter. This drawback will be amplified by using fluid of high viscosity.

Thus the potential of intensification is also strongly linked to the hydrodynamic conditions prevailing in the contactor. This shall depend merely on the nature of the fluid circulating in the lumen of the fibers.

Applications

As example of separations, acid impurities of flue gases like SO_x, NO_x, or even CO₂ can be

removed by contacting the gas feed flow with a liquid properly chosen to trap the acidic species. The gas removal can be due to a physical chemical dissolution of the acid gas into the liquid or to a chemical reaction with the liquid; in this case, the liquid must be endowed of basic properties or contains a solute which is itself a base. When the principle of gas removal is linked to physical chemical affinities, it is wise to operate under pressure to promote higher solubility of the gas into the liquid. On the other case, if a chemical reaction is involved between the gas and the liquid, pressure is not a key parameter.

As example of gas dissolution, one can cite nitrogenation in the beverage industry or blood oxygenation. It is worth to note that blood oxygenation has been one of the very first examples of using membrane contactors in 1975 (Esato and Eiseman 1975); currently the total annual market is above €500 million.

Some examples of use of membrane contactors are listed here:

- Liquid degassing: O₂, CO₂, and N₂ removal from liquids, used for carbonation (food and beverage industry), nitrogenation (microelectronics), deoxygenation, etc.
- Bubble-free gas/liquid mass transfer primarily for ozonation of semiconductor cleaning water
- Dehydration
- Blood oxygenator (health sector)

Genotoxin Removal

Gyorgy Szekely

School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester, UK

Synonyms

Degenotoxification

Definition

Genotoxin removal by membranes is an emerging purification technology aiming to reach ultralow genotoxic impurity levels in order to address health and environmental regulations.

Characteristics

The main challenge of genotoxin removal by membranes lies in the fact that most of them are highly reactive species and thus can attack polymeric membrane framework at molecular level. Degenotoxification of active pharmaceutical ingredients (API) is of utmost importance to drug manufacturers. Genotoxicity of pharmaceutical impurities is being continuously evaluated increasing the list of such highly toxic impurities. Pharmaceutical regulatory authorities draw the attention to API purification and strict the threshold limits of genotoxins via annually issued guidelines. Besides the conventional API downstream processes such as recrystallization, fractional distillation, chromatography, extraction, and adsorbents, new technologies are being implemented in the pharmaceutical industry. Application of nanofiltration alone and combined with adsorbents are proposed as alternative purification technologies assuring ultralow genotoxin contaminations in drug products. API post-reaction streams usually feature organic solvents, limiting the selection of membranes to be used in the process. Commercially available

polymeric and ceramic membranes stable in organic solvents include Koch SelRO, Evonik DuraMem series, SolSep NF series, Borsig GMT-oNF series, as well as Inopor and Pervap ceramic membranes. The feasibility of API degenotoxification by organic solvent nanofiltration (OSN) has been successfully applied in diafiltration mode where fresh solvent is continuously added to the retentate in order to push the relatively small genotoxic molecules through the membrane, while the relatively large API molecules are retained as depicted in Fig. 1 (Szekely 2011). The aim is achieving high genotoxin removal and low API loss which mainly depends on the molecular size gap between the impurity and the API as well as the polarity of the impurity. Hybrid processes featuring OSN and adsorbents have been developed for the removal of genotoxic palladium, impurity retained (Pink 2008), and 1,3-diisopropylurea, API retained (Szekely 2012), from post-reaction solutions. In the former case, the Suzuki post-reaction solution was subjected to OSN, and the palladium was retained by the membrane, while the API was collected in the permeate. On the contrary, in the latter case, the genotoxin was removed with the permeate, while the API was retained. In both cases the genotoxin levels were reduced further by using commercially available adsorbents or tailor-made molecularly imprinted polymers. Not only has the combination of molecular imprinting and membrane technology provided an efficient genotoxin removal process but their fusion as well. Molecularly imprinted membranes (MIM) can also be used for API degenotoxification. Potentially genotoxic 4,4'-methylenedianiline has been applied as a template for MIM adsorbents (De Luca 2011). Environmental and economic analysis proved the sustainability of API degenotoxification by membrane processes in comparison with conventional API purification methodologies such as chromatography and recrystallization (Szekely 2013). Besides pharmaceutical purification, control of genotoxins is also an environmental concern. Nanofiltration featuring DESAL 51 HL, DESAL 5 DL, UTC-20, and UTC-60 membranes was applied for the removal of genotoxic

Germanium Recovery by Ion Exchange Membranes

H. Kawakita
 Department of Applied Chemistry,
 Saga University, Saga, Japan

Germanium recovery using catechol complexation and membrane permeation (also called germanium-recovery-membrane system) is the unique way to recovery germanium. Now, germanium is a rare semimetal and used for semiconductor, catalysis, and optical apparatus. Due to heightened interest in renewable energy sources, the production of solar panels has increased. In production of solar panel, germanium is doped to silicon compound to change the energy gap. Processing of solar panel production generates

Germanium Recovery by Ion Exchange Membranes, Fig. 1 Germanium recovery system using catechol complexation and membrane permeation

the mixed waste of germanium and silicon. For recycling, germanium as a rare metal should be recovered from germanium-containing waste. Using the polymerization technique, the functional group, polyol group, was introduced to the polymerized resin to recovery germanium along with the diffusion. The polyol-containing polymer brush was introduced to the membrane and the germanium solution was flown through the membrane, achieving the high-speed recovery via convection. Catechol forms the complex with germanium as an anion. This complexation occurs selectively compared with silicate ion. We propose the germanium recovery system using membrane and resin, as shown in Fig. 1 (Nozoe et al. 2012): (1) germanium ion selectively forms the complex with catechol in solution, forming anion complex, and (2) germanium complex was captured to the quaternary-amino-group-introduced porous membrane and resin. This study addresses the selective complexation of germanium in the solution and the recovery of anion complex with membrane and resin continuously. In the presence of silicate ion, pH dependence of germanium recovery was checked in a batch mode, as shown in Fig. 2. In lower pH, the selective recovery against silicate ion was achieved in changing the concentration ratio, because the complex formation easily forms in lower pH region. In continuous mode, we determined the breakthrough

Germanium Recovery by Ion Exchange Membranes, Fig. 2 pH dependence of germanium recovery against silicate ion in a batch mode

curves at the initial pH of 2.0 and 11.0, as shown in Fig. 3. At pH 11.0, germanium ion was adsorbed more compared with that at pH 2.0, while the selectivity against silicate ion was higher. This process is applicable for the wastewater of the solar panel containing germanium.

Glass Transition Temperature (T_g)

Johannes Carolus Jansen

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

General Introduction

At the macroscopic scale, the glass transition temperature, T_g , represents the temperature above which a material changes from a stiff glass into a viscous fluid or a rubbery material. Besides polymers, which are the most common materials with a glass transition temperature, also various amorphous solids, organic liquids, alloys, or inorganic glasses may exhibit a glass transition.

At the molecular scale, the T_g of a polymer is the temperature above which large segmental motions of the polymer chains become possible within the time scale of the experiment. The glass transition temperature depends on the molecular architecture. Substituents that restrict the backbone rotation of a very simple polymer, such as polyethylene, will increase its T_g , and the presence of polar groups will have an even stronger effect (Table 1). Besides the substituents on a flexible polymer backbone, the chemical structure of the backbone itself obviously has a major impact on the glass transition temperature. The presence of sterically hindered groups, conjugated bonds, fused rings, etc., increases the glass transition temperature significantly. In the extreme case, the mobility is so much restricted that a T_g is no longer observed. For instance, polymers of intrinsic microporosity (PIMs), a novel class of polymers with growing interest for their high gas permeability (McKeown and Budd 2010), consist of ladder structures with such a high rigidity that large-scale motions are impossible and they do not exhibit a glass transition below their degradation temperature.

Glass Transition Temperature (T_g), Table 1 Glass transition temperature of polymers $[-CH_2CH(R)-]_n$ with the same backbone and different substituents R (Brandrup et al. 1999)

Polymer	R	T_g
Polyethylene	H	155
Polypropylene	CH ₃	258–270
Poly(vinyl fluoride)	F	314
Poly(vinyl chloride)	Cl	354
Poly(vinyl alcohol)	OH	358
Polystyrene	C ₆ H ₅	373
Poly(vinyl acetate)	CH ₃ COO	305

The glass transition temperature of polymer blends depends on their miscibility. In the rare case of miscibility at the molecular level, the glass transition of the blend has a value between those of the neat polymers. Different equations describe the behavior of polymer blends more or less satisfactorily.

In the Fox equation, the T_g of the blend depends exclusively on its composition:

$$\frac{1}{T_g} = \frac{w_1}{T_{g,1}} + \frac{w_2}{T_{g,2}} \quad (1)$$

where w_1 and w_2 are the weight fractions and $T_{g,1}$ and $T_{g,2}$ are the glass transition temperatures of pure polymer 1 and polymer 2, respectively.

The Gordon-Taylor equation is able to describe slightly asymmetric dependencies of the T_g on the blend composition, by means of an adjustable parameter, K_{GT} :

$$T_g = \frac{w_1 T_{g,1} + K_{GT} w_2 T_{g,2}}{w_1 + K_{GT} w_2} \quad (2)$$

The Kwei equation introduces a binary parameter, q , which represents the interaction between the two polymers, and can be used to describe even more asymmetric T_g versus composition profiles (ElMiloudi et al. 2009):

$$T_g = \frac{w_1 T_{g,1} + K_{Kwei} w_2 T_{g,2}}{w_1 + K_{Kwei} w_2} + q w_1 w_2 \quad (3)$$

Glass Transition Temperature Analysis

Besides a change in the mechanical properties, the T_g is also accompanied by a fairly abrupt change

Glass Transition Temperature (T_g), Fig. 1 Schematic representation of a DSC trace (bottom) and of the specific volume (top) of an amorphous polymer

in the specific heat of the sample (Fig. 1). Various other properties undergo more or less pronounced changes at the T_g , such as the density, the specific heat, the elasticity coefficient or Young's modulus, the rate of diffusion of gases or liquids through the polymer, the thermal expansion coefficient, etc.

There is a clear correlation between the glass transition temperature and the transport properties in dense membranes (Matteucci et al. 2006). The gas and vapor permeability is much higher in the rubbery state than in the glassy state, and the selectivity is usually lower. Therefore, the value of the T_g is one of the main parameters influencing the membrane performance. For most other membrane applications, also those using porous membranes, the glass transition temperature is of large interest too. Since porous membranes may collapse upon softening, it is of fundamental importance that they are operated at a temperature sufficiently far below the T_g .

Glass Transition Temperature Depression

Johannes Carolus Jansen
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Glass transition temperature depression is the phenomenon which describes the reduction of the glass transition temperature by external factors, usually by the presence of solvent molecules or of other additives in the polymer matrix. Such additives have the capacity to enhance the mobility of the polymer chains, thus enabling long range motions at lower temperature than in the neat polymer. Although this often goes hand in hand with the phenomenon of plasticization, a reduction of the elastic modulus at room temperature, the two concepts should not be confused. Plasticization strictly refers to the mechanical properties of the polymer and the molecules, which reduce the elastic modulus of a polymer by an increase of the chain mobility generally also reduce their glass transition temperature. The opposite is not necessarily the case and it may happen that an additive, which lowers the T_g , at low concentration increases the elastic or Young's modulus at room temperature. This is then referred to as anti-plasticization.

Glassy Membranes

Johannes Carolus Jansen
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Glassy membranes are membranes consisting of amorphous polymers which are in their glassy state at room temperature or under the normal operation conditions, i.e., their glass transition temperature is above room temperature or the operating temperature. The high stiffness of the glassy polymer provides sufficient mechanical strength to the membranes to exist also as porous or dense integrally skinned flat films or hollow fibers.

The polymer stiffness is an essential aspect in the membrane formation process by non-solvent induced phase inversion, where at a certain point of the process solidification of the polymer is required to consolidate the morphology of the membrane. In glassy polymers, this is typically by vitrification of the polymer when diffusion of the solvent from the polymer rich phase into the coagulation bath leads to a gradual increase of the glass transition temperature until this exceeds the coagulation bath temperature.

Glassy Polymer

Johannes Carolus Jansen
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Strictly, any amorphous polymer is glassy at temperatures below its T_g , but in practice a glassy polymer refers to those polymers which are in their glassy state at room temperature, thus to amorphous polymers with a glass transition temperature above room temperature, in contrast to rubbery polymers, which have a T_g below room

temperature, and (semi-)crystalline polymers with a melting point above room temperature. Under particular circumstances also semi-crystalline polymers can become glassy after quenching, if the crystallization kinetics and the crystal nucleation rate are sufficiently slow to prevent crystallization upon rapid cooling. A typical example of such polymer is poly(ethylene terephthalate), PET.

Glassy polymers are characterized by their high stiffness and amorphous non-crystalline structure. These properties make them size selective in their dense form and also mechanically sufficiently resistant to exist as porous flat film or hollow fibre membranes. Examples of the most commonly used polymers in commercial membranes are cellulose acetate, polysulfone, poly(ether sulfone), polyimide, and polycarbonate.

Global Optimization of Membrane Processes

Radoslav Paulen

Department of Biochemical and Chemical Engineering, Technische Universität Dortmund, Dortmund, Germany

For a number of years, researchers and engineers in many fields have reported the problem of obtaining multiple solutions while solving problems of nonlinear programming (NLP). Multiplicity of solutions is caused by the nonconvex nature being present typically in many engineering problems. Global optimization (GO), sometimes called nonconvex optimization, encompasses several techniques which can be used to handle the problem of finding the best of these solutions, the global optimum.

General form of GO problem is same as for NLP problem and it may be stated as

$$\begin{aligned} \min_x & f(\mathbf{x}) \\ \text{s.t.} & \mathbf{h}(\mathbf{x}) = 0 \\ & \mathbf{g}(\mathbf{x}) \leq 0 \end{aligned}$$

where $\mathbf{x}$ represents vector of optimization (decision) variables, $f(\mathbf{x})$ is optimization criterion, $\mathbf{h}(\mathbf{x})$ and $\mathbf{g}(\mathbf{x})$ stand for vectors of equality and inequality constraints, respectively.

To find the global optimum, many methods have been developed. These can be basically classified into two branches, stochastic and deterministic ones. Stochastic methods (Weise 2007) such as simulated annealing, genetic algorithms, and particle swarm optimization got inspired by natural phenomena. In general, they randomly search through the solution space (space where constraints are satisfied) and due to that usually do not require gradient information. It is often reported that weakness of these algorithms is that they cannot guarantee convergence to global optimum in finite time.

On the other hand, deterministic methods search through the whole solution space systematically and thus can provide so-called ϵ -convergence (ϵ is arbitrarily small positive number) guarantee to the global optimum. Most popular are methods based on branch-and-bound algorithms and interval analysis (Horst and Tuy 1990).

The latter type of methods was successfully used in Chen et al. (2006) for globally optimal design of membrane fuel cell. Other applications of methods of GO involve parameter estimation (Papamichail and Adjiman 2004), optimal control problems (Esposito and Floudas 2000), and problems of nonlinear and mixed integer nonlinear programming (Chachuat et al. 2006). Other references on GO problems in chemical engineering can be found in Rangaiah (2010).

Gluconic Acid Production in Hybrid System Membrane Bioreactor with ED

Zhiwei Wang

Department of Environmental Engineering,
College of Environmental Science and
Engineering, Tongji University, Shanghai, China

Synonyms

Organic acid production by membrane biotechnology with electrodialysis (ED)

Introduction

Organic acids are a group of organic compounds with acidic properties. The most common organic acids are the carboxylic acids (e.g., gluconic acids) containing carboxyl group -COOH and sulfonic acids comprising the group $\text{-SO}_2\text{OH}$. In addition, organic compounds, which have hydroxyl -OH , thiol group -SH , the enol group, and the phenol group that present weak acidity, are also generally referred to as organic acids. Organic acids have been widely used in foods, beverages, pharmaceuticals, cosmetics, detergents, plastics, resins, and other biochemical or chemical products. As a result, they have a close relationship with human's daily life. As one type of organic acid, gluconic acid has been used as food additive, acidity regulator, and chelating agent. Organic acids can be produced by two prevailing

methods, i.e., fermentation and chemical synthesis. In either fermentation or chemical synthesis, separation, concentration, and purification are necessary for the acid production. Due to the excellent performance of membrane separation, membrane technology such as electrodialysis (ED) can provide a novel alternative to conventional procedures for organic acid production (Huang et al. 2007).

ED is a kind of technology which arranges ion-exchange membranes alternately in a direct current field (see Fig. 1). The ion-exchange membranes include cation-selective, anion-selective, and bipolar membranes. ED technology includes conventional electrodialysis (CED), electrometathesis (EMT), electro-ion substitution (EIS), electro-electrodialysis (EED), electrodialysis with bipolar membranes (EDBM), electrodeionization (EDI), and two-phase electrodialysis (TPED), which can be applied for organic acid production (Huang et al. 2007).

Electrodialysis with bipolar membranes (EDBM) has been proved to provide a feasible solution for gluconic acid production (Novalic et al. 2000). EDBM is a kind of technology that integrates solvent and salt dissociation. Compared to conventional organic acid production (precipitation and acidification), it can realize salt conversion without second salt pollution or provide H^+ and $\text{OH}^-/\text{alkoxide}$ ions in situ without salt introduction (Huang and Xu 2006). In lab scale EDBM system for gluconic acid production, the conversion rate of sodium gluconate could reach no less than 98 %, with current efficiency around 70 % and energy consumption about 1 kWh/kg acid (Yu et al. 2000; Huang et al. 2008).

When a reactor or bioreactor is integrated with ED, the combined process can realize in situ separation, purification, and organic acid production adjustment without apparent retrogression in its function. For instance, the use of fermentation to produce acids can be integrated into a membrane bioreactor system coupled with ED. However, some improvements are needed for modifying the technology, which include reducing membrane cost (especially bipolar membrane), improving the antifouling properties of

Gluconic Acid Production in Hybrid System Membrane Bioreactor with ED,

Fig. 1 Schematic of
ED. M^+ : cation; X^- : anion

membranes, and increasing the selectivity for co-ions and developing ion-exchange membranes with a specific selectivity for organic anions or hydrogen ions (Huang et al. 2007). To sum up, membrane biotechnology with ED is a promising solution for organic acid (e.g., gluconic acid) production (See also organic acid production by membrane technology with ED).

Glucosidase in Membrane Bioreactor

Rosalinda Mazzei

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

β -Glucosidase is the enzyme responsible for the oleuropein hydrolysis; it belongs to the group of hydrolases widely existing in various sources, such as fungi, bacteria, plant, and animal tissue. The broad optimum pH and temperature range makes this enzyme particularly useful for application in biotechnology processes. The β -glucosidase from different sources has been studied in various systems, as free or attached to different supports (Yeoh 1991; Esen 1993; Montero and Romeu 1993).

A lot of interest was demonstrated in the enzymatic/substrate system β -glucosidase/oleuropein due to the fact that the oleuropein hydrolysis products are phytochemicals that can be potentially used, if obtained in pure form, in pharmaceutical and food field. In addition oleuropein hydrolysis is very important because it is present in Olive Mill Waste (OMW), following the strategy of waste valorization.

In *in vivo* system, olives and leaves, oleuropein is hydrolyzed by β -glucosidases action. In the first reaction step, the products are oleuropein aglycon with a glucose molecule. Oleuropein aglycon, due

to its poor water solubility, is not yet purified and not yet commercially available, because after its production by enzymatic hydrolysis, it is fastly rearranged into water-soluble compound.

Few examples are reported in the literature in which β -glucosidases are used immobilized on membranes (Mazzei et al. 2009).

A hybrid membrane operation system is developed to (i) compartmentalize the oleuropein hydrolysis, occurring in aqueous phase within the porous membrane, and (ii) separate and stabilize the aglycon, occurring in organic phase at the membrane lumen side interface, based on the membrane emulsification concept.

The biotechnology used to conduct the hydrolysis of oleuropein is a multiphase biocatalytic membrane reactor.

Polymeric membranes were heterogenized with a β -glucosidase. The OMW, containing oleuropein, passed through the enzyme-loaded membrane where the reaction occurred. The water phase containing reaction products passed through the membrane and met an organic phase recirculated into the lumen side where water-in-oil emulsions were formed drop by drop. Droplet size and stability were adapted so that enough exchange area interface was achieved, and once aglycon extraction was completed, droplets broke and phases separated spontaneously. The integrated system biocatalytic membrane reactors and membrane emulsification process showed that it is possible to produce and simultaneously isolate the isomer of oleuropein aglycon in one step, starting from OMW (Mazzei et al. 2009, 2010, 2012; Conidi et al. 2014).

Gold Recovery by Supported Liquid Membranes

Pietro Argurio

Department of Environmental and Chemical Engineering, University of Calabria, Arcavacata di Rende, Italy

Gold is the chemical element which symbol is Au (from Latin *aurum*) and the atomic number is 79. The oxidation states in its compounds range from -1 to $+5$, and Au(III) is the most common. Typical Au(I) complex is $\text{Au}(\text{CN})_2^-$ (in cyanide media) which is the soluble form of gold encountered in mining, while in chloride media Au(III) complexes (Au_2Cl_6) are the typical ones.

Gold production by means of its extraction from mining can represent an important contribution to environmental pollution. Metal ores, which generally contain less than 1 ppm of gold, are ground and mixed with sodium or potassium cyanide for gold chemical extraction. Precious metal and heavy metal impurities such as cadmium, lead, zinc, copper, nickel, and arsenic are usually present in an anionic form (i.e., cyanide salts) after their extraction from metal ores. These salts are toxic to the liver and kidneys because of both cyanide and metal content.

Thus, it would be desirable to be able to selectively remove these complexes for the recovery of precious metals.

Gold, over its use in jewelry, also has a wide use in various industries, thanks to its physical and chemical properties. Thus, the recovery of this metal from the different wastewater generated by these industries is also of growing interest (Alguacil 2004).

Gold can be recovered from different aqueous solutions by various physicochemical separation techniques as precipitation, ion exchange, carbon adsorption, cementation, solvent extraction, etc. In the case of convective solvent extraction, metal ion-containing solution is placed in contact with a large amount of an appropriate organic phase (Kargari et al. 2004). This extraction step is followed by a stripping one. The main drawback of solvent extraction is the large amount of solvent required when dilute solutions were processed, making this process not very cheap and safe, since the used solvents are often chlorinated and sometimes carcinogenic.

Liquid membrane (LM)-based processes have become an attractive alternative to conventional techniques for selective separation and concentration of both organic and inorganic compounds from dilute aqueous solutions since they combine extraction and stripping into a single process, thus reducing the solvent inventory requirement and then cost significantly (Molinari and Argurio 2011). They also allow the use of expensive and highly selective extractants, which otherwise would be uneconomic in solvent extractions.

LM systems include nonsupported liquid membranes (bulk liquid membrane (BLM) and emulsion liquid membrane (ELM)) and supported liquid membrane (SLM). SLMs consist of an organic LM phase impregnated in a thin hydrophobic microfiltration membrane. This LM phase generally contains an extractant (carrier) which binds very selectively the target component in the donor phase (feed), transporting it into the acceptor phase (strip), resulting in the so-called facilitated transport (Molinari et al. 2009a, b).

Referring to gold transport, SLM systems have been tested in the separation of this precious metal mainly from cyanide (Au(I)) or chloride (Au(III)) media. Highly acidic conditions are required for the extraction and transport of Au(III) because of its easily reducible nature.

Various carriers for Au transport across a SLM were reported in literature. Among them, the commercially available extractant Cyanex[®] 921 has been applied in the carrier-facilitated transport of both gold(I) and gold(III) recovery from cyanide and chloride media, respectively (Alguacil et al. 2005). Gold(I) is transported from alkaline pH values (6–11). Gold(I) extraction takes place in that pH range by the following equilibrium reaction:

where the subscripts aq and org denote the species contained in the aqueous and organic phase, respectively, and L represents the extractant.

In the case of gold(III), the extraction is governed by the following pH-dependent equilibrium reaction:

where $n = 1, 2$.

Graft Polymerization

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

Graft polymerization is a process in which monomers are covalently bonded and polymerized as side chains onto the main polymer chain (the backbone).

Grafting is an attractive approach to impart a variety of functional groups to a polymer. Graft polymers are also known as graft copolymer since it contains at least two different kinds of monomer units such as the grafted side chains that are structurally distinct from the main chain. The monomer to be grafted may be of one or more than one type; thus, the graft chains in grafted copolymer may be

homo-polymers or copolymers as illustrated in Fig. 1 (A, B, and C are representing different types of monomers).

Grafting can be accomplished by either “grafting to” or “grafting from” approaches. In “grafting to” approaches, functionalized monomers react with the backbone polymer to form the grafted one. On the other hand, “grafting from” is achieved by treating a substrate with some method to generate immobilized initiators followed by polymerization. High grafting density polymer also can be accomplished using this technique (Bhattacharya et al. 2009).

Graft copolymerization can be initiated by various methods including chemical treatment, photochemical treatment, ionizing radiation (such as gamma radiation, electron beam radiation, etc.), photo-irradiation, plasma-induced techniques and enzymatic grafting, etc. Grafted polymers can be very useful as they can be tailored to the requirements of particular applications by appropriate selection of backbone and monomers to be grafted.

Grafted polymers have wide range of application such as in the field of biomedical, textiles, automobiles, cable technology, separation and purification, electrolyte membranes, coatings, adhesives, laminates, commodity plastics, etc.

Grain Models

Vasilis Burganos¹ and Eugene Skouras²

¹Institute of Chemical Engineering Sciences, Foundation for Research and Technology – Hellas, FORTH/ICE-HT, Patras, Hellas

²Institute of Chemical Engineering Sciences, Foundation for Research and Technology, Hellas, Patras, Hellas

Grain models involve a set of grain-shaped objects to represent the solid phase in the interior of porous materials. Model representation of the structure of porous membranes is very important for visualizing and understanding the structure of amorphous, porous, and random membrane materials and can be implemented, among other ways, by deterministic or stochastic modeling of the outcome of the actual fabrication process (e.g., random assembly or sequential deposition of particles) with or without reference to the detailed physics of the process (Preparata and Shamos 1985). Typically, such reconstructions involve some random packing, optionally combined with ballistic deposition of hard or soft spheres, disks, or ellipsoids of prolate or oblate geometry (Rogers 1964). This stage is usually followed by simulation of grain sintering as the result of thermal or viscous sintering. In the majority of packing procedures, random sequential deposition of overlapping or non-overlapping particles takes place (Jaeger and Nagel 1992). The particles position themselves either randomly or under the influence of some unidirectional force (ballistic) or,

alternatively, toward some fixed center of attraction (Finney 1970). Ballistic random sphere packs are usually driven by gravity and are considered to be more representative of the compaction process. Ballistic deposition and central attraction methods provide packings with similar structural properties in terms of the autocorrelation function. Depending on the type of fabrication process as well as on the characteristic dimensions of the grains, other forces, either local/short ranged (van der Waals, double layer, hydrodynamic) or long ranged (electrostatic, electromagnetic), can also be taken into account during simulations. One, two, or three points of contact can be assumed to discontinue the downhill motion of the particle. In energy-based models, downhill motion of a particle continues until a position of local energy minimum is reached that is considered stable. Such a procedure can be systematically followed through the use of a steepest descent method followed by a conjugate gradient algorithm (Conway and Sloane 1993). Procedures based on Monte Carlo or similar statistical methods have also been implemented, where each time a number of test grains are inserted, but only selected displacements are allowed that lead to minima of position or energy. Motion and interaction of granular particles have also been studied mechanistically with computational methods, such as the discrete element method (DEM), also called a distinct element method (Zhu et al. 2007, 2008), for computing the motion and effect of a large number of small particles. Although DEM is closely related to molecular dynamics, the method is generally differentiated by its inclusion of rotational degrees of freedom, as well as compacted and other complex granular geometries. Grain models have also been used for the description of micro- or nanoparticle additives, also called nanofillers (at least one of the particles' dimensions is in the nanometer range), into a polymer membrane to form a polymeric composite membrane or a hybrid, mixed matrix membrane (Sanchez et al. 2005). This is a promising idea to improve the separation properties of the neat polymer and produce the so-called nanobarriers with numerous applications in gas separation, fuel cells, preservation of sensitive products, etc. The enhancement of

Grain Models,

Fig. 1 Ballistic reconstruction followed by partial sintering

barrier properties through the addition of inorganic nanoparticles in polymer matrices can be studied with the help of grain models and elucidate their complex dependence on interfacial interactions, filler shape and orientation with respect to the transport direction, filler size, distribution of inter-filler distances, and degree of agglomeration (Fig. 1).

Granular Media Pretreatment Filtration

Graeme K. Pearce
Membrane Consultancy Associates Limited,
Reading, RG8 7EJ, UK

Definitions

The term *granular media filtration* refers to the use of packed bed of granular media to provide a filtration stage between a raw water intake and a final advanced treatment stage.

Objectives

The objectives of pretreatment using a granular media filter are to remove a proportion of particulate constituents that would otherwise foul a downstream treatment stage such as reverse osmosis or ion exchange. If combined with the use of chemicals, or if the media acts as a biofilter, the granular media filtration stage can be used to reduce the concentration of dissolved organics as well.

Description

In a granular media filter, the feed passes through a packed bed of granules, and contaminants are progressively removed. Due to the ability of the filter to continue removing particles as the feed progresses through the bed, these filters are sometimes referred to as “depth filters,” though this generic description also covers other types of filtration device.

The simplest granular media filter is a sand filter. The original slow sand filters used a very low filtration velocity and relied on capturing particles on the surface where a biologically active layer formed (the “schmutzdecke” layer). Rapid gravity filters (RGF) using sand media were developed more than 100 years ago to increase filtration capacity and reduce the footprint required. These rapid sand filters used a much higher linear velocity and a deep bed of granules to increase dirt-holding capacity and convert the device from a surface filter to a depth filter (Richardson et al. 2002).

The granular media filter is a development of these early sand filters. Different types of media are combined in current commercial products to optimize performance. Generally, the filter operates with a downflow loading cycle in which particles are removed from the feedstream. A periodic cleaning cycle is then undertaken referred to as backwash in which the flow direction is reversed, i.e., normally in upflow. The flow rate during backwash is sufficient to cause the bed to expand in volume, though it is not fully fluidized. The efficiency of the backwash flow may be well enhanced by the introduction of air known as air scour.

Particle Removal Mechanisms

Filtration devices such as membranes or screens use a surface removal mechanism to capture particles. The smallest particle that can pass through such a filter is equivalent to the largest pore or aperture in the surface of the filter. The dirt-holding capacity of surface filters is limited by the area of the filter surface in contact with the

feedstream. Surface filters tend to be used for feeds with a low solids content and need to be cleaned regularly in order to have a commercially useful performance. The surface removal mechanism is at its most useful in two situations, namely for particles which are quite large, e.g., $>100\text{ }\mu\text{m}$, as for a screen product and for quite small particles, e.g., $<10\text{ }\mu\text{m}$, as for a membrane.

Between these ranges, ie for particle sizes of 10 to $100\text{ }\mu\text{m}$, the depth or gravity or depth filtration mechanism becomes very useful, since products which use this mechanism have a high dirt-holding capacity combined with an acceptable removal efficiency. The granular media filter is the most common example of a device which operates using this type of mechanism to remove particulates from a feedstream (Voutchkov 2010). These filters have a nominal pore size considerably greater than the particles they are capturing. Thus, for a sand filter with a grain size of normally $500\text{ }\mu\text{m}$ (i.e., 0.5 mm) or greater, the nominal pore size of the media is more than $100\text{ }\mu\text{m}$, and there is a wide distribution of channel sizes. In fact, the absolute rating of such a filter will be of the same magnitude as the particles used to form the media bed. However, the bed can routinely capture particles down to $10\text{ }\mu\text{m}$.

The key attribute of the granular media filter is that the pore size at the surface of the bed is much greater than most of the particles in the feed challenge. Particles can therefore enter the media and start to travel with the feed flow through the bed as illustrated in Fig. 1. Potential capture sites are created in the bed wherever particles pass close to a grain of the media. Gravity forces attracting the particle to stick to the surface of a grain overcome the viscous drag forces which would tend to displace the particle from the surface and continue in suspension in the fluid flow.

For small particles, the forces of gravity attraction are relatively weak; hence this type of filtration mechanism is only effective down to a certain particle size, typically around 5 or $10\text{ }\mu\text{m}$. Below that, the gravity attraction forces diminish sharply, reducing by a factor of 1,000 for every order of magnitude (ie factor of 10) reduction in particle size, since the mass is related to the diameter by a cube law.

Granular Media Pretreatment Filtration, Fig. 1 Granular media bed cross section illustrating particle capture mechanism

Due to the depth of the media and the tortuous path created for the feed as it moves through the bed, relatively high removal rates can be achieved, even for particles significantly below the nominal pore size. Media beds of 500 μm sand particles can achieve removal efficiencies of 90–99 % for particles down to 10–20 μm . The nominal rating of the depth filter means that the removal efficiency is variable and is dependent on a host of environmental and operating parameters.

A limitation in this type of device is that large particles can bridge the pores at the surface, creating a cake layer. This effect is known as surface blinding, and if it happens, it prevents the efficient utilization of the pores in the depth of the media, bringing the filtration cycle to a premature end. The surface of the media therefore requires protection with a coarse pretreatment. Typically, a screen with a 300 μm rating is used to prevent blinding.

Although high removal ratings can be achieved for a granular media filter removing particles well

below that of the nominal pore size, the removal efficiency is much lower during the initial ripening period in which the media is “conditioned” by particles in the challenge. The conditioning particles form a fine surface coating on the media which enhances removal. In addition, the filter rating declines toward the end of the cycle as the differential pressure increases across the bed assisting the viscous drag from the fluid flow to dislodge any loosely attached particulates.

Media Characteristics

Media Type

Granular media products can utilize several different media types of different grain sizes and bed depths to form the deep bed filter. The basic media used in the devices include anthracite (a type of coal) and sand, with the additional option of a layer of garnet. It is also quite common to use granular activated carbon (GAC), potentially in addition to anthracite. Anthracite can allow a

biofiltration mechanism to develop in which bacterial colonies supported on the surface of the media consume dissolved organic carbon, thereby improving organic removals. GAC enhances biofiltration characteristics, but note that it can take 4–6 weeks for the bacterial colonies to become fully effective. Generally, the holdup time in the media bed needs to be at least 15 min for biofiltration to be effective.

A contrasting approach is to apply a chlorine residual to the feed to enhance filtration performance and maintain disinfection in the bed. Cl_2 oxidizes a wide range of the contaminants in the feed improving removal efficiencies.

Number of Layers: Single or Multimedia

The simplest granular media filters just use a single type of media, usually sand, but also possibly GAC. A typical rating for such a filter is 20 μm . Standard pretreatment filters use a layer of coarse anthracite followed by a layer of fine sand, the so-called dual media filter (DMF) to provide a 10 μm rating. The media is chosen so that the specific gravity of the upper layer is less than that of the lower layer in order to maintain stratification in long-term use (Wilf 2007).

For finer filtration duties of about 5 μm , a triple media filter can be used in which a final layer of high density garnet provides a polishing step. There are also commercial products using four layers, which allow higher velocities and therefore smaller footprint. Four-layer filters claim to achieve removals down to 1 μm or even lower. Multilayer filters require grains with good sphericity so that the stratification can be maintained after backwashing.

Velocity Range

A single layer filter would tend to use a flow rate of 5–12 m^3/h per m^2 of surface area of the bed, i.e., a linear velocity of 5–12 m/h (2–5 gpm/ft^2). The velocity can be increased with the number of layers and depth of the layers, depending on the degree of removal required. DMF pretreatment plants normally have a velocity of 8–12 m/h . Four-layer filters can be operated at 25–60 m/h , a factor of five times as high as a single media, which reduces footprint significantly.

Polyelectrolyte addition to the feed can also be used to increase velocities, and this is standard practice where footprint is of critical importance, e.g., offshore.

Grain Size Diameter: Coarse Versus Fine

A typical grain diameter can vary from 0.5 mm for a fine bed filter to 1.5 mm for a coarse bed. In a DMF of anthracite and sand, it is common to use an initial layer of coarse anthracite followed by a fine layer of sand to provide a graded bed with finer removal performance nearer the outlet. Higher velocities are used for coarse beds.

Bed Depth: Shallow Versus Deep

The total bed depth of a shallow filter could be around 1 m, whereas a deep bed filter could be from 2.5 to 3.0 m in depth (Voutchkov 2010). An allowance of about 5 % needs to be provided to allow for settlement. For a shallow bed filter treating a good quality feed, a typical DMF bed depth would be 0.5 m of anthracite followed by 0.5 m of sand. A poorer feed quality would require greater depth of up to 1.5 m for each layer. For a filter providing a biofiltration action, a deep bed would be required.

Product Characteristics

Pressure Versus Gravity

A pressure filter encapsulates the media bed in a large pressure vessel, of 2.4 m or up to 3 m in diameter. Although ideally suited for small or medium-sized plants, they are sometimes used for larger plants in which there is an advantage to maintain the pressure head of the feed. Pressure systems also have the advantage of smaller footprint and shorter construction times.

The other type of configuration is the gravity filter in which the media bed is contained in a large tank, potentially made from concrete. Gravity filters are often used where there is no disadvantage in breaking the pressure head of the feed and where the plant layout lends itself to the use of gravity to drive the feed through the bed. Gravity filters are also normally preferred for plants with a high capacity.

Vertical Versus Horizontal

Vertical filters tend to be used for smaller flows, whereas it is more economical to use a horizontal arrangement for higher flow rate. The horizontal configuration can have flow distribution problems during backwash, but this can be overcome by compartmentalizing the vessel, with independent backwashing of each part.

Downflow Versus Upflow

Granular media filters can operate in upflow or downflow configurations, but in a pretreatment context, it is more common for them to be operated with downflow. Downflow has benefits in dealing with algae, since the potential for algal cell rupture is reduced.

Number of Filtration Stages

For a good quality feed, a single-stage DMF would probably be selected, but for a poor quality feed of say >20 NTU, it is common practice to utilize two-stage filtration in which a high rate rapid filter is followed by a slow rate fine bed. Two-stage filtration tends to reduce coagulant use for a given removal. It is quite common to adjust the coagulant dose and/or pH between stages to optimize the overall performance.

Process Sequence

A typical filtration cycle for a granular media filter will be at least 8 h and more probably up to 24 h or even more. Treated water quality will be less good during the ripening period which could last up to 30 min, and some or all of the flow will be wasted or more likely recycled during this period.

After the filtration cycle, a backwash step is carried out. During the backwash step, water passes through the filtration bed in the reverse direction causing bed expansion and removal of deposits. Backwash operation is usually conducted at flow rate of twice the filtration cycle flow, e.g., a typical range of 16–24 m/h for a DMF. Bed expansion during backwash is in the range of 20–50 %. With increased water temperature, the backwash flow rate has to be increased by about 3 % per °C to maintain bed expansion due to lower viscosity of the backwash fluid.

Backwash is mainly conducted with filtered water. In seawater RO plants, RO concentrate is sometimes used for filter backwash to improve recovery. The backwash operation is sometimes combined with air scouring to improve the efficiency of bed expansion and the removal of deposits. Air mixed with backwash water passes through the filtration bed at rate of 55–90 m/h (3–5 scf/ft²-min). Air scouring increases bed expansion and is therefore followed by a high rate water backwash.

The typical backwash sequence takes 3–10 min using an air and water mixture, followed by high rate backwash for 5–10 min. The total backwash volume is typically 2–3 % of the filtrate. Backwash is triggered by a timer with a high differential pressure override.

Process Design

Figure 2 shows a typical process design for a granular media filtration stage in a seawater reverse osmosis (SWRO) desalination duty (Voutchkov 2010).

The pressure drop in a packed bed is related to the velocity of flow through the bed and the characteristics of the media and the feed as shown by the Ergun equation (Richardson et al. 2002). The first term in this equation is dominant for the laminar flow regime and the second becomes dominant for turbulent flow.

Ergun equation:

$$\frac{\Delta P}{L} = \frac{150 V_s \mu (1 - \varepsilon)^2}{D_p^2 \varepsilon^3} + \frac{1.75 V_s^2 \rho (1 - \varepsilon)}{D_p \varepsilon^3}$$

where

Δp is the pressure drop across the bed.

L is the length of the bed.

D_p is the equivalent spherical diameter of the packing.

ρ is the density of fluid.

μ is the dynamic viscosity of the fluid.

V_s is the superficial velocity (i.e., the velocity that the fluid would have through the empty tube at the same volumetric flow rate).

ε is the void fraction of the bed (typically 0.6 for sand grains).

Granular Media Pretreatment Filtration, Fig. 2 Conventional RO pretreatment process

The equation applies for a clean bed. As solids are captured from the feed, the characteristics of the bed such as the voidage will change and the pressure drop will rise. Granular media filters have relatively large channels, which means that both lamina and turbulent terms in the equation make important contributions. For media with much finer channels, such as membranes, the flow regime is almost exclusively laminar.

The equation shows that physical characteristics for the bed such as the sphericity of the particles and the voidage between them are important factors in determining pressure drop. In the first term (characteristic for a laminar regime), pressure drop is inversely related to the channel diameter, whereas in the second term (which contributes for a turbulent regime), the pressure drop is inversely related to the channel diameter squared, thus becomes much more important for coarser beds.

Operational Issues

At the start of a filtration cycle, granular media filters normally operate with a low pressure drop. For a shallow bed DMF operated at a moderate rate, the pressure drop will be less than 0.1 bar. During a filtration cycle, the pressure drop will rise to around 0.25 bar. It is important that the pressure drop does not rise too much or channeling may occur in the bed leading to breakthrough. When this happens, the excessive pressure drop causes particle movement in the bed such that low resistance channels open up in low voidage zones of the bed resulting in by-passing. If the particles have good sphericity and are closely packed, it would take a high pressure drop for this to happen, but for

a randomly packed bed formed after expansion during backwash, the bed is prone to this effect.

Channeling can also occur at the vessel walls, and for this reason, the vessel diameter should ideally be 1500 times the mean particle diameter, a criterion which is readily achieved in large-scale commercial units.

A key problem for granular media filters can be biofouling since the extensive surface of the bed can support bacterial colonies which are provided with nutrients from the dissolved organic carbon content (Wilf 2007). Indeed, this action can be intentional and is the basis of biofiltration. The behavior is referred to as biofouling if growth increases to the point that pressure drop becomes excessive. The phenomenon can be controlled by dosing an oxidizing agent such as chlorine, though this might just transfer the biofouling issue to downstream units due to the formation of readily assimilable organic by-products. A strategy to control the problem is to use shock chlorination in which a high chlorine concentration of 5 ppm free residual or more is dosed intermittently, for example, on a daily basis, for a short period of say 30 min.

Filtered Water Quality

Filtrate quality is determined through measurement of turbidity and SDI. There is no defined and consistent correlation between turbidity and SDI. However, field experience indicates that to achieve an SDI below three, the filtrate turbidity has to be below 0.1 NTU, preferably below 0.05 NTU. By choosing an appropriate filtration system design in terms of media type, bed depth, and number of layers, a turbidity of 0.3 NTU can

easily be achieved, and operators target 0.1 NTU or less with a two-stage system.

Dissolved organic carbon (DOC) removal is an important requirement for granular media filtration since this material can cause fouling of downstream RO by direct adsorption and by supporting biofouling. A high level of DOC may increase turbidity and SDI, but there is no simple direct correlation.

Chemical dosing holds the key to achieving low turbidity filtrate, normally using a clarification or flotation stage. A single-stage system usually achieves a modest reduction in DOC of 20–30 %, whereas a two-stage system may achieve 60–70 %. Due to the depth removal mechanism, there will be some degree of variability in the treated water quality achieved as feed quality varies and other seasonal changes occur.

Among the allotropes of carbon (2D) (Fig. 1), the graphene is one of the most attractive materials

formed by a single layer of sp²-bonded carbon atoms arranged in honeycomb lattice with the atomic thickness of 0.4 nm and a light weight of 0.77 mg/m².

In graphene, the carbon atoms are bonded with three neighboring carbon atoms by planar σ orbitals, which are separated by 120 °C with each other, while pi (π) orbitals are delocalized above and below the graphene sheet (Fig. 2a). Taking into account the electronic configuration of the carbon at the ground state (1s²2s²2p²), the carbon-carbon σ orbitals are covalent bonds deriving from hybridization of the single 2s orbital with two 2p orbitals; these bonds confer robustness and elasticity to the graphene structure. Indeed, a stiffness of 300–400 N/m and a breaking strength of 42 N/m have been estimated for defect-free graphene sheet (Lee et al. 2008). Also, graphene sheets show a spring constant of 1–5 N/m for thickness of 2–8 nm, resulting in a great ability to recover the initial size after strain. These outstanding mechanical properties make undoubtedly the graphene a desirable material for reinforcing objects and devices as well as for the construction of graphene-based nano-electromechanical systems (NEMS) (Bunch 2007).

The pi (π) orbitals are instead formed from overlapping of neighboring 2pz perpendicular to the graphene plane (Fig. 2b); the bands π (bonding) and π^* (antibonding) represent the valence band (VB) and the conduction band (CB), respectively, through which the electrons can be delocalized providing excellent electronic properties to the graphene. The mobility of pi (π) electrons is indeed estimated to be 15,000 cm² V⁻¹ s⁻¹ with hypothetical limits of 200,000 cm² V⁻¹ s⁻¹ for free-impurity sheets. Also, the resistivity of the graphene is assessed to be 1.0 10⁻⁸ Ωm at room temperature with a capability of the material to transfer electrical current over 10⁸ Acm⁻². The bands through which the electrons move are represented as two cones touching at the Dirac crossing energy point (Fig. 2c). These two bands, however, degenerate at the corner, the so-called Dirac point or “K” of the hexagonal Brillouin zone, thus resulting in a semimetal with a zero-bandgap due to the

Graphene Membranes, Fig. 1 Carbon allotropes where graphene sheet is the key component: graphene (2), fullerene (0D), nanotubes (1D) and graphite (3D)

identical environment of two carbon atoms located in the unit cell of the graphene lattice (Fig. 2a) (Lau 2012). This could represent a limitation for the use of graphene in electronics, optoelectronics, photonics, bio-sensing, and solar energy harvesting. Nevertheless, the application of an electrical field can induce changes in the Fermi level, thereby causing doping or holes events (Lu 2013). When the Fermi level is above the Dirac point, there are holes in the VB. On the contrary, a predominance of electrons is in the CB when the Fermi level is over the Dirac point. In both the cases, electrons and holes enable the graphene to be transformed from semimetal to semiconductor with much higher conducting properties. This approach, along with the exceptional capability of the “charge carrier” to travel sub-micrometer distances without scattering, opens new horizons and promising perspectives in the development of new approaches for mass production of high-quality semiconducting graphene at low costs.

Currently, the graphene can be produced according to some techniques, including mechanical exfoliation, epitaxial growth, and graphene oxide (Soldano 2010). As always, the choice of each single-manufacturing approach implies advantages and disadvantages, respectively. The mechanical exfoliation takes the advantage to be handled and competitive from the economics point of view, but the technique is not reproducible and reliable enough to be scaled up. The growth of graphene on metallic substrates by chemical vapor deposition (CVD) of hydrocarbons is another possible route for synthesizing single layers of graphene on larger scale, in spite of the high-processing temperatures. However, structural quality and preserved electronic properties represent two important challenges to reach yet. The chemical exfoliation is regarded as a promising scalable and handling approach for mass production of graphene sheets. It relies on the use of reactants in the interspace between graphene layers, thus

Graphene Membranes, Fig. 2 (a) Honeycomb lattice of graphene with hybridized sp^2 -bonded carbon; (b) delocalized electrons in π (π) orbitals above and below the graphene sheet; (c) the Dirac point or “K” of the hexagonal Brillouin zone

promoting weak interactions such as van der Waals forces and making the exfoliation easier than micromechanical cleavage, wherein cohesive forces between layers and long-distance interactions take place between graphene and substrate. The problem is a partial change in the carbon hybridization from sp^2 to sp^3 due to the oxidation of graphene. The latter is surely an interesting precursor of graphene derivative, but its electronic properties are different from semi-metallic graphene produced according to the other approaches.

However, the use of graphene in membrane separation processes requires some expedients, including controlled nanoporation, modulated layers' inter-distance, and chemical functionalization of the layers, in order to make this already excellent electronic material also an outstanding interface for selective gas separation,

water purification, and (bio)sensors (Xu 2015; Smith 2013; Gugliuzza 2014).

Graphene sheets have been recently proposed as barrier membranes against water and gases for applications in food and pharmaceutical packaging. The related impermeable properties are ascribable to the high density of delocalized electrons, which prevent molecules from passing through the hexagonal rings. Recent density functional theory studies have however demonstrated how the creation of functionalized sub-nanosized holes (around 3 Å) in graphene sheets can enhance the selectivity for the H_2/CH_4 gas pair (Tsetseris and Pantelides 2014). Specifically, values of selectivity of 10^8 for H_2/CH_4 may be obtained through graphene sheets with nitrogen-functionalized pores while selectivity of 10^{23} for H_2/CH_4 by using graphene with all-hydrogen passivated pores (Fig. 3).

Graphene Membranes, Fig. 3 Representative scheme of graphene with functionalized nanopores, defects, and wrinkles responsible for selective behavior

These pores represent a barrier (1.6 eV) for CH_4 , whereas H_2 (0.22 eV) can pass easily. Therefore, the creation of nanoporous in graphene together with the occurrence of local defects and wrinkling and variation of the layer thickness, but also the insertion of functional groups in the pore edges or between the stacked layers, have been simulated to make the graphene selective for gases such as He, Ne, H_2 , CH_4 , and CO_2 (Gadipelli and Guo 2015).

Electron beam, ultraviolet-induced oxidative, etching of holes on graphene surfaces together with the use of molecular building blocks lithography, and tethering of graphene with carbon nanotubes have been proposed to produce nanoporous graphene-based membranes through the deposition of graphene sheets onto substrates, including the polymeric ones. However, it should be better to purify the gas mixtures before passing the pores molded in graphene, since impurities, molecular residues, could obstruct severely the diffusion pathways and affect the selectivity properties. Despite that various predictive studies indicate the nanoporous graphene and derivate such as graphene oxide as excellent materials for gas mixture separation, a lot of academic and industrial research is still necessary to develop on large scale products with suitable structural and chemical fruitful features for scaled applications in gas separation.

Water purification and desalination represent another challenge to reach by using graphene-based membranes as well (Xu 2015). Perforated

graphene with pores of the order of nanometers are big enough to let water pass through, but somewhat small to stop pollutants and salts at the interface. Pore size, layer inter-distance, and functionality together with pore wettability are again parameters to be considered for the optimization of the productivity and efficiency of water purification. Concerning the selectivity of the membrane process, rejection mechanisms based on size exclusion, chemical and electrostatic interactions, and Donnan's exclusion have been proposed. Computational studies concerning, as an example, the separation of NaCl from water have evidenced that small and hydrophobic pores enable at low pressure the rejection of NaCl according to size exclusion mechanisms, while bigger ions in the absence of hydrogen bonding could increase the energy barrier to the ion passage. Ionic exchange mechanisms have been also detected through graphene oxide membranes for the separation of acid from FeCl_3 solutions. The transport of ion H^+ has been estimated to be two orders of magnitude greater than Fe^{3+} ions (Sun 2014).

Some hypotheses of mechanisms for water permeation through graphene and graphene oxide membranes have been also suggested, including capillary-driven flow between a water monolayer and the pristine graphene layer and passage through porous microfractures formed in the graphene sheets. The latter have been envisaged as critical elements for enhancing water permeation, while hydrophilic groups attached to the

Graphene Membranes, Fig. 4 Scheme of an unstrained (a) and strain (a') graphene layer over a cavity. Scheme of a functional graphene sensor-based device (b)

graphene oxide have been regarded as responsible for slowing down the flux due to the establishment of hydrogen bonding between water and oxidized regions of graphene. On this basis, well-sized interlayer gaps and broader nanochannels through graphene or graphene oxide are expected to well retain salt ions and undesired organic compounds, while the water permeation is expected to increase over three orders of magnitude with respect to traditional commercial reverse osmosis membranes.

Undoubtedly, membranes prepared from perforated and functionalized graphene represent an attractive solution to the incessant requirement of highly performing gas and liquid separations. The outstanding mechanical properties together with the predicted ultrafast permeance and high-retention power make this class of membranes promising candidates for gas separation and water purification processes. However, a lot of explorative research is required to optimize mass production of high-quality, durable, and energy-efficient graphene wherein the formation of nanopores and the insertion of functional moieties between the stacked layers can be perfectly controlled in number, shape, and size without yielding mechanically vulnerable points. Also, the resistance of this kind of materials to swelling and fouling and ion clogging, which often take place during separation processes, needs to be detected as well as the ability to work under high pressure and harsh conditions. It is auspicious that computational and experimental studies can be reciprocally validated, thus casting new light on predominant transport mechanisms. In this way,

the design of well-defined structure can be addressed at overcoming the performance of traditional membrane separations on larger scale.

Theoretical and experimental studies have also confirmed the high potential of graphene for nanoelectromechanical system (NEMS) applications, where electrical conduction and outstanding mechanical and optical properties (i.e., a transparency with a transmittance that changes from 95 % to 70 % for thickness ranging from 2 to 10 nm with an absorption of 2.3 % of white light) can be combined (Bunch 2007). As an example, graphene sheets exhibit a pressure sensitivity of two- to tenfolds superior to the standard silicon- or carbon nanotube-based micro-electromechanical sensors (MEMSs). Despite that graphene has no band gap, such the piezoelectrical properties cause changes in the electronic structure under strain (up to 23 %) resulting in a shift of the Fermi level (Smith 2013). When used as pressure sensors, freely suspended graphene membranes can sense a gradient of pressure established between the external surrounding atmosphere and the unchanged internal environment, which is regarded as the result of no permeability of graphene sheet to air. This gradient of pressure yields a proportional force, thus causing the expansion of graphene and, consequently, a variation of the resistance with enhancing of the electrical charge transfer (Figs 4a-a'). This ability of the graphene membranes makes them extremely promising materials for controlling and monitoring actions in the field of automobile, aerospace, textiles, and weather.

Despite those proof-of-concept demonstrations (Fig. 4b), graphene membranes have been also proposed as chemical (e.g., small organic compounds and ions) and biological (e.g., sugars, proteins, DNAs) sensors enabling to reveal an increase in the current passage as an effect of doping generated by interactions between the functional graphene sheet and specific analyte (Liu 2012). As a chemical sensor, a recent membrane integrated with single-walled carbon nanotubes, which are regarded as rolled graphene sheets, has been proposed for detection and regulation of surrounding humid atmosphere (Pingitore 2015). Graphene membranes are expected to have enhanced performance.

Similarly to gas and water separation, a deeper understanding of the mechanisms which regulate recognition and interactions and signal transmission are necessary in order to promote technology transfer and commercial application of devices realized according to reliable, reproducible, and scalable manufacturing processes.

Overall, the use of graphene could lead to a completely novel membrane with well-organized ultrathin nanocomposite architecture. They may promote very high selectivity thanks to precise pore morphology control as well as high permeability thanks to a very thin layer. Furthermore, energy use can be minimized, thanks to facilitated transport promoted through the membrane by favorable surface interactions.

Production of ultrathin nanocomposite membranes is challenging to produce, and therefore, it is difficult to predict the real commercial promise. However, the importance of energy reduction in massive production, such as seawater desalination, provides a crucial driver, which will foster the development of these novel membranes.

Hydrogen permeation

Palladium is known to be one of the most effective metals for hydrogen adsorption, dissociation, and recombination even though the permeability of this metal is by an order of magnitude lower than that of refractory metals such as tantalum, vanadium, and niobium.

In 1863, Sainte-Claire Deville and Troost discovered that hydrogen is able to permeate through palladium; later, in 1866, Graham found that palladium can absorb huge amounts of hydrogen (several times with respect to its initial volume) at room temperature. The palladium-based membrane technology for hydrogen production has come into life in the late 1950s. In the 1960s, pioneering studies by Gryaznov led to the development of a breakthrough membrane reactor when palladium-based membranes were

used for hydrogen supply or withdrawal from the reaction zone, thus providing improved yield and high catalyst effectiveness (Pagliery and Way 2002).

Hydrogen permeation through solid palladium proceeds via the solution–diffusion mechanism, and this mechanism involves the following steps: (a) diffusion of molecular hydrogen to the surface of the palladium-based membrane, (b) a reversible dissociative adsorption on the palladium surface, (c) dissolution of atomic hydrogen in the bulk metal, (d) diffusion of atomic hydrogen through the bulk metal, (e) association of hydrogen atom on the palladium surface, (f) desorption of molecular hydrogen from the surface, and (g) diffusion of molecular hydrogen away from the surface (Yun and Oyama 2011). On the palladium surfaces, the dissociative adsorption of hydrogen molecules proceeds with a low or zero activation energy barrier. This is the first step in bulk absorption toward the formation of metal hydrides.

Generally, hydrogen permeation is described by the following equation:

$$J = P(p_h^n - p_l^n)/L,$$

where J is the hydrogen flux, P is the permeability coefficient, L is the thickness of the palladium layer, p_h and p_l are the partial pressures of hydrogen on the high-pressure (feed) side and the

low-pressure (permeate) side, respectively, and n is the pressure exponent. This exponent generally ranges from 0.5 to 1 depending on the rate-controlling step [steps (a–g)]. According to Sievert's law, when the rate-controlling step is the bulk diffusion through the palladium layer [step (c)], the n value is equal to 0.5 because the diffusion rate is proportional to the concentration of hydrogen atoms on the opposite sides of the metal surface and this hydrogen concentration is proportional to the square root of the hydrogen pressure. When mass transport to or from the surface (a, g) or dissociative adsorption (b) or associative desorption (e) becomes rate-controlling steps, the expected value of n is 1 because these processes depend linearly on the concentration of molecular hydrogen. In the case of the Pd-based composite membranes with thick ($>5\ \mu\text{m}$) Pd layers, the n values are higher than 0.5, and this fact can be explained by defects or pinholes through which substantial amounts of hydrogen can permeate. This process proceeds via the Knudsen or Poiseuille flow mechanisms, and the corresponding exponents are higher than 0.5.

In the case of binary palladium alloys, hydrogen permeation is generally proportional to the average bond distance of the alloys. Permeability is the product of diffusivity and solubility. In the case of Pd–Ag alloys, hydrogen solubility increases with increasing Ag content up to 20–40 wt.%; hydrogen diffusivity decreases with increasing Ag content. Concomitant changes in solubility and diffusivity lead to higher hydrogen permeability (1.7 times higher) as compared with that of pure Pd at 23 wt.% of Ag and at 623K (Ma et al. 2003).

Hairy Superhydrophobic Surface

Wolfgang M. Sigmund and Shu-Hau Hsu

Department of Materials Science and Engineering, University of Florida, Gainesville, FL, USA

Department of Energy Engineering, Hanyang University, Seoul, Republic of Korea

Superhydrophobicity not only exists on lotus-like leaves but also on surfaces comprising high-aspect ratio soft hairs. Although the piliferous exterior is found in almost all water-repellent arthropods and has been noted for over 100 years, (Comstock 1887) compared to the Lotus effect, studies based on this structure are relatively limited. The superhydrophobicity is dominated by both surface roughness and chemistry, so as the hairy superhydrophobic surfaces. Surface roughness arises from the arrangement of hairs, and, similar to the water-repellent leaves, hairs are also covered with a layer of epicuticular wax that renders the exterior hydrophobic and prevents the penetration of water. The wax layer is not only important in water repellency but also in water retention within the insect's structure; removal of the waxy layer will result in rapid desiccation of the insects (Wigglesworth 1945).

The hairs in almost all water-repellent arthropods are generally arranged as a series of “I” shapes. Most of the hairs are not only inclined but curled with their tips parallel to the bodies, which in turn provides a greater resistance to wetting. The array of tilted pillars increases the pressure required to penetrate into the grooves, as the free space between the tilted pillars is reduced, making them favorable to resisting water. A horizontal array of cylindrical pillars also provides a greater water resistance (Extrand 2002). Overall, a series of inclined and parallel pillar arrays is energetically unfavorable for a liquid to intrude between the pillars parallel to the interface.

Figure 1 shows an example of typical hairy superhydrophobic surface, water strider's body and its leg (Hsu 2010). Two different sets of

Hairy Superhydrophobic Surface, Fig. 1 SEM images of the hair layer of the water strider's body. The hair tips are bent inward toward the body to enhance the degree of

water repellency. (a) The hair on strider's abdomen is tilted at around $30\text{--}45^\circ$ relative to the body surface. (b) The hair on strider's leg (Hsu 2010)

H

Hairy Superhydrophobic Surface, Fig. 2 A water droplet forms a spherical bead on Lady's Mantle leaf

body hair can be usually found from the arthropods. Longer hairs, termed macrotrichia, are less dense with lengths of 20 mm and diameters of around 1 mm, and shorter hairs, termed microtrichia, are approximately 2 mm long and 100 nm wide. Longer hairs taper to a point from the base and incline at an angle of $30\text{--}45^\circ$ with their tips parallel to the body surface. Shorter hairs are however highly dense and are more randomly oriented. The hair is also patterned with nanoscaled grooves with widths of around 400 nm, thus providing a structure with hierarchical roughness. Many arthropods possessing hairy integument are reported to have contact angles

reaching over 160° , and it provides crucial living functions for the species, such as underwater respiration, walking on water, or surviving under rain impact (Bush et al. 2008). More details on underwater respiration can be found in the section of plastron effect.

Hairy leaves with a feature similar to *lotus effect* are also common. These plants, i.e., Lady's Mantle (*Alchemilla vulgaris*), exhibit a plurality of flexible hairs, termed trichomes, on their leaves and stems (Fig. 2). Water droplets on the fuzzy leaves can be suspended by the trichomes, which effectively prevent the droplets from wetting the leaf. Although the leaf itself

shows an excellent hydrophobicity, those trichomes are found to be hydrophilic (Otten and Herminghaus 2004). Water droplets are pinned by the hydrophilic trichomes causing high contact angle but roll-off angle.

Halar

Anna Maria Bertasa
Solvay Specialty Polymers, Bollate (MI), Italy

Halar[®] ECTFE (ethylene chlorotrifluoroethylene) is a semicrystalline fluoropolymer based on ethylene and chlorotrifluoroethylene. It is currently utilized in several demanding market segments where high purity, outstanding resistance to harsh environments, low permeation, and high temperature stability are needed. Examples of applications are chemical processing, semiconductors, wire and cable, and the pharmaceutical industry.

Meltblown filters made by Halar[®] ECTFE are commercially available for pharmaceutical applications, solvent filtration, and semiconductor applications where high ozone resistance is needed. Other possible applications of Halar[®] ECTFE membranes are membrane contactors, including membrane distillation, pervaporation, and industrial water treatment.

The following features make Halar[®] ECTFE a suitable material for manufacturing membranes for specialty applications:

- Stability at pH levels ranging from 1 to 14
- Outstanding resistance to organic solvents, ozone, and chlorine
- Very good tensile properties
- High temperature stability – continuous use up to 150 °C
- Melt processability, including TIPS (thermally induced phase separation) technology for membrane manufacturing
- Low level of extractible
- FDA compliance for selected grades

The general physical properties of the Halar[®] ECTFE grades available for membrane applications are shown in Table 1.

Because of its exceptional chemical resistance, Halar[®] ECTFE cannot be processed via solution phase inversion. It must be processed at temperatures close to its melting point (200–240 °C) using a TIPS process for manufacturing hollow fiber and flat sheet membranes. Typical diluents used to process this material are high boiling solvents such as acetyl tributyl citrate, glycerol triacetate (GTA), dibutyl phthalate (DBP), and dioctyl phthalate (DOP) (Simone et al. 2012). The polymer should be melt blended with the selected solvent, casted or extruded into the desired form, and cooled at a temperature that promotes phase separation. As final step the diluent should be extracted from the membrane, typically with a low boiling solvent that is mixable with the diluent.

Phase diagrams of Halar[®] ECTFE are available in the literature (Ramaswamy et al. 2002), together with examples of processing for manufacturing membranes and membrane properties (Roh et al. 2010). For example, when using

Halar, Table 1 General physical properties of Halar[®] ECTFE commercial grades

Halar [®] grade	Melting point	Melt flow index	Tensile modulus	Contact angle
	Tm (°C)	g/10 min at 275 °C	MPa	
Halar 901	242	1 @ 2.16 kg	1,600–1,800	90–95°
Halar 902	222	1 @ 5 kg	1,600–1,800	90–95°

DBP as solvent, it is possible to obtain a liquid-liquid demixing for polymer concentrations below 25 % and solid-liquid demixing with polymer crystallization for polymer content above 25 %. It is possible as well to extend the liquid-liquid demixing region of the phase diagram by changing the polarity of solvent, for instance by adding a non-solvent in the polymer mixture.

It is possible to manufacture either flat sheet either hollow fiber membranes with Halar[®] ECTFE. The equipment must be properly designed taking into consideration the needed processing temperature; its corrosion resistance in contact with fluoropolymers must be verified before use.

Porosity of membrane can vary from MF to UF according to processing parameters, such as polymer concentration, type of solvent, processing temperature, air gap, and cooling rate; it is possible as well to obtain symmetrical or asymmetrical structures and to fine tune the thickness of the skin layer (Müller 2006).

Halar[®] ECTFE is a hydrophobic material due to its chemical composition. Surface properties can be modified with posttreatments that are typically performed at industrial level for obtaining desired performances of the finished membranes.

Halophiles

Chiara Schiraldi and Mario De Rosa
Department of Experimental Medicine, Section of Biotechnology, Medical Histology and Molecular Biology, Second University of Naples, Napoli, Italy

Halophiles (i.e., “salt loving”) are organisms that live in high salt concentrations. In taxonomy most of them belong to the Archaea kingdom, but also *Halobacteria* and some Eukarya were isolated. Often they are colored orange, red, or pink/purple; colonies are evidencing the presence of carotenoids and bacteriorhodopsin. The latter is used to absorb light, which provides energy to create ATP. *Halobacteria* also possess a second pigment, halorhodopsin, which pumps chloride ions in the cell in response to photons, creating a voltage gradient and assisting in the production of energy from light. A number of species have been isolated in oceans but also in environment with salt concentration much higher than marine ones like in salty lakes (e.g., Dead Sea) or in evaporation ponds. Halophiles, both aerobes and anaerobes, may use a variety of nutrients and energy sources. Anaerobic ones include phototrophic, fermentative, sulfate-reducing, homoacetogenic, and methanogenic species. Halophiles require NaCl for growth, while halotolerant organisms can stand saline conditions up to 0.8 M NaCl, moderate halophiles prefer salt concentration in the range 0.8–3.4 M, and finally extreme halophiles grow at higher concentrations up to 5.1 M NaCl (Oren 2002a). These microorganisms have evolved physiological and genetic characteristics to cope with the increase in osmotic pressure in different ways. The extremely halophilic Archaea accumulate ions such as K⁺; other bacteria developed biosynthetic pathways to synthesized

compatible solutes (e.g., glycine, betaine, sugars, polyols, amino acids, and ectoines) in high concentration so as to make the cytoplasm isotonic with respect to the surrounding medium; besides, they often present efficient ion pumps, UV-absorbing pigments, and acidic proteins, which help them to resist the osmotic stress and the denaturing effects of salts, as well as intense solar radiation. Many of these characteristics constitute valuable resources for biotechnology and nanotechnology (Oren 2002b). Salty food bioprocessing and fermentation (such as soy sauce, Chinese fermented beans, salted cod, salted anchovies, sauerkraut, etc.) often involve *Halobacteria*, as either essential ingredients or accidental contaminants. Besides these food applications, compatible solutes, which are small biomolecules that also help to protect cells against stresses like high temperature, desiccation, and freezing, have now been used for 15 years in cosmeceutical products. These peculiarities improved performances of moisturizers and other products, thus prompting the research on bioprocess improvement. Recently, using ectoine-excreting strain *Halomonas salina* DSM 5928(T), a new process was developed by Lang and co-authors (2011) for high-efficiency production of ectoine, which involved a combined process of batch fermentation to grow cells followed by a resting cell production phase. Hydroxyectoines were efficiently produced using a microfiltration membrane bioreactor (Schiraldi et al. 2006). More recently also the production of mannosylglycerate (MG) was established through the milking process. In particular the trehalose-deficient mutant of the strain *Thermus thermophilus* RQ-1 was cultivated using upshock fermentation and osmotic downshock, for the effective production/excretion of MG. More than 90 % of the intracellularly accumulated solute was recovered from the water fraction. Although currently established applications of halophiles are limited primarily to compatible solutes in the cosmetic industry and carotene and hydrolases in the nutritional and food industries, many other novel applications are under development. They include specialized applications for films of bacteriorhodopsin from halophiles for a variety of optical

nanodevices, including high-capacity computer storage; some subcellular components, such as polyhydroxyalkanoate granules, gas vesicles, and phospholipid vesicles, and bioactive compounds like halocins are being developed for medical applications. Last but not least, important metabolic activities of halophiles have also been tapped for a variety of environmental applications and specifically for bioremediation of pollutants in saline wastewaters.

Heat and Mass Transfer in Membrane Distillation

Chunrui Wu

State Key Laboratory of Hollow Fiber Membrane Materials and Membrane Processes, Institute of Biological and Chemical Engineering, Tianjin Polytechnic University, Tianjin, China

Membrane distillation (MD) is a membrane separation process based on the principle of evaporation which uses hydrophobic membrane as separating medium. Unlike the membrane process of ultrafiltration (UF) and reverse osmosis (RO) which only contain mass transfer, MD also contains heat transfer and the heat transfer is a key factor affecting mass transfer efficiency. So the investigation of heat and mass transfer in MD process is the key to explore the mechanism of MD process. Many scientists have made

Heat and Mass Transfer in Membrane

Distillation, Fig. 1 Heat transfer resistances in membrane distillation

Heat and Mass Transfer in Membrane

Distillation, Fig. 2 Direct contact membrane distillation

significant progress in the study of heat and mass transfer in MD process.

Heat Transfer

The heat transfer of MD consists of three steps, as shown in Fig. 1. First, heat transfer by the way of convection in the feed boundary layer. Second, heat transfer by the way of conduction through the membrane and the heat flows together with the vapor through the membrane pores, i.e., the latent heat of vaporization. Third, heat transfer by the way of convection in the permeate boundary layer. All types of MD contain the first two steps, while for the third step, other types of MD do not contain it except DCMD.

At steady state, the overall heat transfer coefficient (H) of the MD process can be expressed by a resistance in series model (M. Khayet et al. 2000):

$$\frac{1}{H} = \frac{1}{h_f} + \frac{1}{h_m + J\Delta H_v / \Delta T_m} + \frac{1}{h_p}$$

where h_f , h_m , and h_p are the individual heat transfer coefficients of liquid feed phase, membrane,

and permeate, respectively; ΔH_v is the heat of vaporization and ΔT_m is the temperature drop across the membrane.

For MD process, heat and mass transfer occur simultaneously and result in complex heat transfer mechanisms. So the mass transfer can affect both heat transfer rates and heat transfer coefficients. The heat transfer model has been proposed to describe the heat transfer mechanisms in MD and facilitates the evaluation of the membrane surface temperatures. In most literatures, the heat transfer model for MD was developed based on the assumption of linear temperature profile and isenthalpy flow of vapor (Figs. 2, 3, and 4).

The effective energy transferring from the feed bulk to the membrane surface is:

$$Q_f = h_f(T_f - T_{fm})$$

The energy transferring across the membrane is:

$$Q_m = J\Delta H + \frac{h_m}{\delta}(T_{fm} - T_{pm})$$

For the VMD process, the contribution of heat conduction in the membrane matrix

Heat and Mass Transfer in Membrane

Distillation, Fig. 5 Mass transfer resistances in membrane distillation

membrane and high operating temperature as well (Phattaranawik and Jiraratananon 2001). Moreover, the heat transfer by convection is ignored in the MD process, except in AGMD (Curcio and Drioli 2005).

Mass Transfer

The mass flux (J) in MD process is assumed to be proportional to the vapor pressure difference across the membrane and is given by:

$$J = C_m(P_f - P_p)$$

where C_m is the membrane coefficient, P_f and P_p are the vapor pressure at the membrane feed and permeate surfaces, which can be calculated from the Antoine equation (Fig. 5). For different types of MD processes, the obtainment of C_m is based on different models:

For DCMD process, mass transfer through the membrane can be divided into three models. These models relate the mass transport with collisions between molecules, and/or molecules with membrane. Knudsen diffusion takes place when the pore size is too small, such that the collision between the molecules and the inside walls of the membrane suitably expresses the mass transport and the collision between molecules can be ignored (Zhongwei et al. 2003). Molecular diffusion occurs when the molecules move corresponding to each other under the influence of concentration gradients. In Poiseuille flow (viscous flow), the gas molecules act as a continuous fluid driven by a pressure gradient.

In AGMD process, the molecular diffusion theory is used to describe the transfer of vapor molecules through the membrane and the air gap. A stagnant gas film (air) is assumed to lie inside the membrane at the air gap side.

For VMD process, in order to remove air trapped in the membrane pores, the deaeration of the feed solution or a continuous vacuum in the permeate side should be applied. Consequently, the ordinary molecular diffusion resistance is neglected. The Knudsen mechanism is used to express the mass transfer (Bandini and Sarti 1999), Poiseuille flow, or both together (Banat and Simandl 1994).

Heavy Metal Recovery by Chelating Agents and Membranes

Jose Sabate

Department d'Enginyeria Agroalimentaria i Biotecnologia, Universitat Politècnica de Catalunya, Castelldefels, Spain

Heavy metal concentration from wastewaters can be carried out by several membrane operations. Electrodialysis (ED), reversed osmosis (RO), and nanofiltration (NF) membranes retain polyvalent cations. Alternatively, heavy metals can be concentrated by polymer-enhanced ultrafiltration (PEUF) as well.

Further, membrane separations, combined with other process, can contribute to heavy metal recovery from groundwater, contaminated soils, sediments, sludge, etc (Dermont et al. 2008; Hashim et al. 2011; Tsang et al. 2012). First of all, heavy metals must be extracted from the solid matrix using a washing solution containing a suitable extractant. The huge amount of metal-containing solution produced can be concentrated by membrane technologies with the concomitant production of a clean permeate solution, which ideally should be reused.

Metal extraction efficiency depends on several factors such as extractant/metal affinity, extractant/metal ratio, leaching method, liquid/solid ratio, pH, and extraction time. Heavy metal extraction has mainly been done by solutions of strong acids, chelating agents, dendrimers, surfactants, or reducing or oxidizing agents (Dermont et al. 2008). All of them but acid extraction takes place under mild conditions preventing structural changes in the matrix to be decontaminated.

The most used chelating agents are EDTA (ethylenediaminetetracetic), NTA (nitrilotriacetic acid), and DTPA (diethylenetriaminepentaacetic acid). They form very stable chelates and they are very efficient in removing heavy metal ions bound to mineral and organic fraction of soil (Hashim et al. 2011). One of their drawbacks is their low selectivity, which involves high reagent consumption due to the complexation of Ca and

Fe. Further, they show a low biodegradability, and biodegradable chelating agents such as EDDS ([S,S]-ethylenediaminedisuccinic acid), IDSA (iminodisuccinic acid), MGDA (methylglycinediacetic acid), and citric acid have been receiving increasing attention in recent years.

Because of their molecular size, chelates can be concentrated by nanofiltration, but previously, colloids that can clog the NF membranes have to be removed by microfiltration or ultrafiltration. Recycling the chelating agent improves the economical competitiveness of the process and diminishes the environmental impact, especially for nonbiodegradable chelating agents. That involves separating metal and ligand in the contaminated washing solution. Ion exchange resins and selective precipitation of metal or chelating agents by addition of chemical agents have been proposed. Experiments at laboratory scale have showed that some NF membranes are able to reject Cu^{2+} while citric acid leaks. That can be achieved in acidic conditions when the chelate is broken and NF membrane is positively charged, which favors the rejection of Cu^{2+} cations and the leakage of neutral or slightly negatively charged citric acid.

Some water-soluble polymers contain ligand groups that can form chelates with heavy metals as well. They can be retained by ultrafiltration membranes. At low pH, metal ions are released from the polymer and a new ultrafiltration operation allows one to separate them. The polymer can be regenerated by alkali addition and reused. This process is named polymer-enhanced ultrafiltration (PEUF). Recently, dendrimers, highly branched macromolecular compounds with suitable terminal functional groups, have been tested for heavy metal recovery from contaminated soil.

Heavy Metal Recovery by Membrane Operations

Jose Sabate

Department d'Enginyeria Agroalimentaria i Biotecnologia, Universitat Politècnica de Catalunya, Castelldefels, Spain

Several industries such as metal plating facilities, mining operations, fertilizer industries, tanneries, batteries, paper industries, pesticides, etc., produce heavy metal (Cd, Cr, Cu, Hg, Ni, Pb, Zn) wastewaters. Heavy metals are not biodegradable and persist in the environment: waters, soils, sediments, etc. Further, their recovery could be attractive from the economical perspective, and several technologies have been studied and proposed to carry it out: chemical precipitation, ion exchange, adsorption, membrane filtration, coagulation-flocculation, flotation, and electrochemical methods (Coman et al. 2013; Fu and Wang 2011; Kurniawan et al. 2006). Membrane separation technologies yield a high efficiency and allow continuous operation. However, to prevent membrane clog, a pretreatment of the polluted effluent to achieve a clean feed is required. Further, they need careful operation and periodic washing to prevent membrane damages and fouling.

Membrane separations can reduce the volume of contaminated water, making the next processes necessary to full recovery easier and cheaper. At the same time, a clean permeate that meets the applicable effluent guidelines is obtained. That

can be achieved with high efficiency using various membrane technologies: ultrafiltration (UF), nanofiltration (NF), reverse osmosis (RO), and electrodialysis (ED) (Coman et al. 2013; Fu and Wang 2011; Kurniawan et al. 2006).

UF membranes reject macromolecules, but their pores are not small enough to retain heavy metal ions such as Cd^{2+} , Cu^{2+} , Hg^{2+} , Ni^{2+} , Ni^{3+} , etc. Nevertheless, they can be concentrated with the addition of a soluble polymer or surfactant that binds the metal ions. Those processes are named polymer-enhanced ultrafiltration (PEUF) and surfactant-enhanced ultrafiltration (SEUF) (Coman et al. 2013; Fu and Wang 2011; Kurniawan et al. 2006). At low pH, metal ions are released from the polymer and a new ultrafiltration operation allows one to separate them. The polymer can be regenerated by alkali addition and reused.

RO is used to remove almost everything from the water which includes small molecules and ions. It can produce drinking water from brackish water or seawater. Therefore, it has been shown to concentrate heavy metal ions such as Cd^{2+} , Cu^{2+} , and Ni^{2+} . However, compared to other membrane technologies, RO requires the highest pressure and energy cost.

Nanofiltration (NF) is the intermediate process between UF and RO (Soldenhoff et al. 2005). NF membranes usually have an electrical charge, positive for pH values lower than the membrane isoelectric point (IEP) and negative for higher pH values. NF yields high rejections of heavy metal ions, although NF membrane pores are larger than heavy metal ions in solution. That is due to the contribution to the separation process of several mechanisms: steric (sieving), electric (Donan), and dielectric (born and image forces). Dielectric and Donan effects strongly favor the rejection of polyvalent ions. That makes NF very suitable for heavy metal concentration, which can be done in one step and at lower pressure and energy cost than RO.

Electrodialysis (ED) is another membrane process for the separation of ions that uses an electric field as the driving force. It is an alternative to RO for the production of drinking water. It has been demonstrated to be able to concentrate hexavalent

and trivalent chromium and Cd^{2+} , Cu^{2+} , Co^{2+} , Ni^{2+} , and Fe^{3+} .

Membrane technologies can contribute to the heavy metal recovery from contaminated underground water, soils, sediments, sludge, etc. However, a previous extraction of metals is needed, which can be achieved with acids, chelating agents, dendrimers, or surfactants.

Heavy Metal Recovery by Polymer-Enhanced UF

Jose Sabate

Department d'Enginyeria Agroalimentaria i Biotecnologia, Universitat Politècnica de Catalunya, Castelldefels, Spain

Polymer-enhanced ultrafiltration (PEUF) is one of the membrane operations that can be used to separate or concentrate heavy metal from

liquid streams. It is also called polymer-assisted ultrafiltration (PAF), complexation-ultrafiltration process (CUFP), or polymer-supported ultrafiltration (PSU) (Rivas et al. 2009).

Ultrafiltration membranes reject macromolecules, but their pores are not small enough to retain heavy metal ions such as Cd^{2+} , Cu^{2+} , Ni^{2+} , Ni^{3+} , Hg^{2+} , etc. Nevertheless, if a soluble polymer able of binding polyvalent cations is added to a solution containing heavy metal ions (F), the resulting metal-polymer complex will be retained by UF membranes. Then, a clean permeate (P) can be obtained and the heavy metals will be concentrated in the retentate stream (R). See figure 1.

The polymers contain functional groups such as amine, carboxylated, phosphonic, or sulfonate which link to metals either through ionic or chelating bonds. The most used synthetic polymers are polyacrylic acid (PAA) and polyethyleneimine (PEI) (Rivas et al. 2009). The use of natural polymers (chitosan, humic acids, etc.) and polymers anchored on the membrane represents growing alternatives.

A suitable polymer should have a high affinity for target ions and should be able to be recycled in order to make the process economically feasible. It should be biodegradable to prevent new environmental problems, but it cannot have a very short half-life in working conditions. As commercial or natural polymers have a molecular weight distribution, they must previously undergo a diafiltration process to remove short chains, which would bind heavy metals but would leak through the UF membrane. Further, its interactions with membrane materials should be considered to minimize fouling.

Modeling PEUF has usually been carried out through the classic complexation (or exchange ions) equilibrium reactions. For instance, the union between a heavy metal ion, M^{m+} , and a neutral ligand group of the polymer, L, can be represented by the following chemical equilibriums and their respective constants:

For $n=1, 2, 3, \dots$

Heavy Metal Recovery by Polymer-Enhanced UF, Fig. 1 Scheme of PEUF. (F: feed, R: retentate, P: permeate).

The protonation of the L group is described by:

High values of β_n indicate a strong affinity between polymer and target ion. Generally, the basic forms of ligands ($R-COO^-$, $R-NH_2$, etc.) bind the metal ions, but the acid forms ($R-COOH$, $R-NH_3^+$, etc.) do not do it. This fact can be used for polymer recycling. When an acid is added to the metal-polymer complex solution, metal ions are shifted by protons from the ligand sites. A second ultrafiltration operation yields to a permeate containing free heavy metal ions and a retentate with polymer. The polymer can be regenerated by the alkali addition and therefore reused. The global process requires the consumption of an acid and an alkali, and it is a concentration operation as the permeate in acid medium contains most of the heavy metal from the initial contaminated water, but in a smaller volume.

Nanofiltration and reverse osmosis membranes are able to retain and therefore concentrate heavy metal ions without the need of chemical addition. Nevertheless, they require higher pressures and energy consumption than UF. Selectivity is an additional advantage of PEUF as β_n values are particular for any metal-polymer pair.

Micellar-enhanced ultrafiltration (MEUF) is a similar process to PEUF. Instead of a polymer, a surfactant solution over the critical micellar concentration is used. Micelles bound to metal ions and are large enough to be rejected by UF membranes (Mungray et al. 2012).

Hemodialysis (HD) Membranes

Michel Jaffrin

Department of Biological Engineering,
Technological University of Compiègne,
BP 20529, Compiègne Cedex, France

Introduction

Hemodialysis (HD) consists in recirculating the patient's blood into a hemodialyzer with an ultrafiltration membrane which permits to remove uremic toxins mainly by diffusion, while excess

water is removed by ultrafiltration. The treatment of chronic renal disease requires three dialysis sessions of 4 h per week, as well as dietetic restrictions to limit potassium intake. In 2008, 1.58 millions of patients were treated by HD worldwide. Without reuse, assuming a mean membrane area of 0.9 m^2 per hemodialyzer, they would have consumed $213 \cdot 10^6 \text{ m}^2$ of membrane per year. If 75 % of dialysis centers reuse dialyzers 2.54 times (Chuang et al. 2008), this consumption is reduced to $116 \cdot 10^6 \text{ m}^2$, which is still the biggest application of membranes. The first disposable hemodialyzers were commercialized in 1950, but it is the arteriovenous shunt invented by Dr. Scriber from Seattle which permitted modern dialysis by connecting the dialyzer inlet to an arm artery and the outlet with an arm vein, permitting a blood flow rate of 200–300 ml/min into the dialyzer.

Physiological Requirements

Dialysis must reproduce the four main functions of kidney:

- Elimination of uremic toxins, urea, creatinine, uric acid, phosphates, and sulfates
- Removal of excess body water by ultrafiltration, 1–3 L per run
- Control of plasma electrolytes concentrations Na^+ , Cl^- , K^+ , Ca^{++} , by adjusting dialysate ionic concentration
- Maintaining blood pH to 7.2 through an acetate or bicarbonate buffer in dialysate

In regular hemodialysis, only the excess water is removed by ultrafiltration, while in hemodiafiltration (HDF) about 10–20 L of water is removed from blood per session to eliminate toxins and middle molecules by convection in addition to diffusion, and it is replaced by a sterile dialysate except for the part corresponding to excess water. Figure 1 illustrates the difference between HD and HDF. In predilution mode, the sterile dialysate is reinjected in blood at dialyzer inlet, while it is reinjected at outlet in postdilution. Hemofiltration (HF) is analogous to HDF with up to 25 L water removal, but without feeding dialysate in the dialyzer as toxin removal by diffusion is not necessary.

Hemodialysis (HD) and Hemodiafiltration (HDF)

Hemodialysis (HD) Membranes, Fig. 1 Difference between HD and HF modes

Dialysis Membranes

They are divided into two categories, low and middle permeability cellulosic membranes and high permeability polymeric membranes, which are listed in Table 1. They are generally of hollow fiber geometry (200 μm diameter), but some flat sheet membranes are also available. Cuprophane membranes are now replaced by cellulose acetate or triacetate which is more biocompatible, even though they activate complement and leukocytes, leading to inflammatory reaction (Bouré and Vanholder 2004). Masking hydroxyl groups increases their biocompatibility. High permeability membranes permit to carry out hemodiafiltration and hemofiltration treatments with high water removal, partially replaced by sterile dialysate. In addition, polymeric membranes are often more biocompatible than cellulosic ones. They are also superior for patient quality of life, reducing $\beta_2\text{-M}$ amyloidosis, infections, and loss of residual kidney function.

Hemodialysis (HD) Membranes, Table 1 Hemodialysis membranes

Type	Plane	Fiber	Manufacturer		Permeability ml/h-mmHg m ²
			Membrane	Dialyzer	
Low and middle permeability,					
Cuprophane	X	X	AKZO	Baxter, Bellco, Gambro	2–3.5
Cuprophane HDF	X		AKZO	Gambro	8
Cuprophane TAF		X	Terumo	Terumo	
Hemophane	X		AKZO	CD Medical	
Cellulose acetate	X				5
Cellulose triacetate	X			Baxter, Nipro	
High permeability					
PMMA		X	Toray	Toray	14
Polyacrylonitrile PAN	X	X	Hospal	Hospal, Asahi	25
PAN S		X	Hospal	Hospal	40
Polysulfone		X	Fresenius	Fresenius	30–40
Polysulfone		X	Amicon (HF)	Amicon	50
Polyamide		X	Gambro (HF)	Gambro	30

High-flux membranes with larger pores increase removal of middle molecules such as β_2 -microglobulin, cytokines, resistin, immunoglobulins, parathyroid hormones, and dinucleoside polyphosphates. Their removal protects the patient against cardiovascular problems and other side effects of uremic syndrome (Vanholder et al. 2011).

Characteristics of Recent European Hemodialyzers

Hospal Gambro (Meyzieu, France) commercializes three high-flux hollow fibers dialyzers: the Evodial with heparin grafted to AN membrane, giving very good hemocompatibility; the Nephral ST with PEI, a biopolymer grafted on AN69; and the Revaclear with a Poractron membrane permitting to reduce its area. Gambro (Sweden) sells, for HF and HDF, the polyflux H with a polyamide–polyacrylether sulfone membrane. Fresenius Medical Care (Germany) commercializes high-flux dialyzers with a Helixone membrane, the FX60, 800, and 1,000 with urea clearances of up to 278 ml/min at a blood flow of 300 ml/min, and other dialyzers with polysulfone membrane, both at high flux (F 40S to F80S with area from 1 to 1.8 m²) and at low flux (F4HPS to F8HPS with area from 0.7 to 2.4 m² according to patient weight).

Heterogeneous Ion-Exchange Membranes

Mitsuru Higa

Graduate School of Science and Engineering,
Yamaguchi University, Ube, Yamaguchi, Japan

Heterogeneous ion-exchange membrane consists of finely powdered ion exchanger and a binder polymer, and, in many cases, the membrane is reinforced by woven cloth or net to improve its mechanical properties. In general, heterogeneous ion-exchange membranes (IEMs) are prepared by the following method (Sata 2004): finely powdered organic and/or inorganic ion exchanger is homogeneously mixed and heated with a thermoplastic polymer such as poly(vinyl chloride),

Heterogeneous Ion-Exchange Membranes, Fig. 1 Schematic diagram of heterogeneous IEMs with various kinds of shapes

Heterogeneous Ion-Exchange Membranes, Fig. 2 Tubular-type heterogeneous IEM, EDCORE

polyethylene, polypropylene, or other engineering plastics, and then the mixture is formed into the membrane by pressing and/or heating. Heterogeneous IEMs have slightly lower electrochemical properties: lower permselectivity for counterions and/or higher membrane resistance than homogeneous ion-exchange membrane. However, heterogeneous IEMs are easily prepared and have high mechanical strength. Moreover, the IEMs of various kinds of shapes can be easily prepared by pressing and/or heating as shown in Fig. 1: (a) commercial flat-sheet IEMs such as Ralex CMH and AMH (Mega a.s., Czech Republic), (b) profiled IEM for reverse electrolyte applications (Vermaas et al. 2011), (c) hollow fiber-type IEMs (Kiyono et al. 2004), and (d) commercial tubular-type IEMs (EDCORE,

Astom. Co., Ltd., Japan). EDCORE is a membrane electrode apparatus, with smooth-surfaced seamless and tubular IEMs (Fig. 2), and is used in industries such as electro-deposition painting of automobile, building materials, house appliance, and other applications due to their high mechanical strength and ease of handling.

Heterogenization or Immobilization of a Catalyst

Enrica Fontananova
 Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The heterogenization or immobilization of a catalyst in/on a membrane consists in the

incorporation of a catalyst in/on a membrane by chemical bonds or physical entrapment.

In the case of a homogeneous catalyst, the incorporation constitutes a way to heterogenize it.

When a catalyst is incorporated within or on the surface of a membrane, the membrane composition (characteristics of the membrane material, hydrophobic or hydrophilic, presence of chemical groups with specific functionality, etc.) and the membrane structure (dense or porous, symmetric or asymmetric) can positively influence the catalyst performance, not only by the selective absorption and transport of reagents and/or products but also influencing the catalyst activity by electronic and conformational effect.

The main requirements that must be considered to produce an “ideal catalyst” are: low costs, high selectivity, high stability under reaction conditions, nontoxicity, “green properties,” and first of all recoverability, i.e., the possibility to recover and reuse the catalyst (Gładysz 2001; Hill 1999).

In this perspective, the heterogenization of catalysts has interesting implications because it allows the reuse several times of the same catalyst. Among the different heterogenization methods, the entrapping of a catalyst in/on a membrane offers new possibility for the design of new catalytic processes.

In addition to the fundamental criteria that have to be considered in the selection of a membrane for a specific separation process, i.e.:

- Stability (mechanical, thermal, and chemical)
- Permeability and selectivity
- Fouling tendency
- Cost (capital and operating)

Extra technical complexities need to be considered in the design and realization of catalytic membranes:

- Catalyst stability during the immobilization procedure
- Influence of the catalyst particles on the membrane properties (mechanical, transport, etc.)
- Effect of the catalyst loading, dimensions, and distribution, on the catalytic efficiency

- Leaching out from the membrane of the catalyst

However, catalytic membranes deserve special advantages that in many cases justify these additional efforts.

In the design of a catalytic membrane, major issues in the polymer selection are the mechanical, thermal, and chemical stability under reaction conditions.

What is fundamental is to realize a stable catalyst immobilization in order to avoid its leaching out from the membrane. Different immobilization strategies can be used in order to achieve these goals: covalent bonds, electrostatic and weak interactions (van der Waals or hydrogen bonds) of the catalyst with the membrane, or catalyst encapsulation.

A good affinity for the catalyst is desirable in order to avoid catalyst leaching and to have a good adhesion between the polymer and the catalyst, with an optimal dispersion of the second one.

The affinity between a compound and a polymeric material can be often anticipated by the calculation of the *affinity parameters* (Van Krevelen 1990; Barton 1990). These parameters reflect the ability to form hydrogen bond, polar, and van der Waals interactions in condensed phase.

The polymer/catalyst affinity can be also improved by an appropriate chemical functionalization of one or both components.

In the case of application in liquid phase, ideally, the solvent used for the reaction needs to be a non-solvent for the catalyst, and the membrane has not to have an excessive swelling in it.

It is also possible in some cases to improve the catalyst retention in the membrane by the catalyst enlargement as: dendrimers, hyperbranched polymers, and catalyst bound to a soluble polymer (Dioos et al. 2006).

Mass transfer of the reagents to the catalytic sites, and of the products away from them, should be fast enough in order to not limit the reaction, but, at the same time, the contact time catalyst/reagent should be also appropriate.

For a porous membrane, the choice of the polymer material is of less importance for

transport properties in comparison with a dense membrane, because permeation does not take place through the polymer matrix, but through the membrane pores (Vankelecom 2002).

However, the membrane material is relevant for the membrane stability and surface properties, such as wettability and fouling tendency.

The membrane preparation conditions depend on the membrane material and the desired structure and morphology. In the case of a catalytic membrane, the incorporation of the catalyst complicates the process because the catalyst should be firmly entrapped in the membrane and the catalyst structure and activity has to be preserved during the membrane preparation procedure.

Moreover, the properties (including transport properties) of the catalytic membrane are usually different than those of the reference membrane prepared in the same conditions but without the catalyst.

Different techniques for membrane preparation are today available and can be opportunely employed also to prepare catalytic membranes: phase separation, coating, interfacial polymerization, sintering, stretching, and track etching are some examples (Strathmann et al. 2006).

In some cases, the catalyst is entrapped in/on the membrane already formed, by covalent bonds, electrostatic interactions, absorption by weak interactions, or physical entrapment. In alternative, the catalyst immobilization can be carried out in the same time of the membrane formation, for example, by dispersing the catalyst in the polymer casting solution and successive phase separation (Drioli and Fontananova 2010).

Heteropolyacid Composite Membranes

Enrica Fontananova

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Heteropolyacid composite membranes are membranes functionalized with heteropolyacids (HPAs).

Acid catalysis and catalytic oxidation are two of the main application areas of HPAs composite membranes. Moreover, interesting examples of HPAs immobilized in membranes are present in the field of the polymer electrolyte membrane fuel cells (PEMFCs) (Norby 1999).

There are many different structural types of HPAs, but the Keggin type (Mioč et al. 2005) is the most common for the majority of the applications as catalysts or solid state proton conductors.

The HPAs discussed in the following text are molybdophosphoric acid ($\text{H}_3\text{PMo}_{12}\text{O}_{40}$), phosphotungstic acid ($\text{H}_3\text{PW}_{12}\text{O}_{40}$), and silicotungstic acid ($\text{H}_4\text{SiW}_{12}\text{O}_{40}$).

Catalysis by heteropoly acids has well-established industrial applications including heterogeneous catalyzed selective oxidations (oxidation of methacrolein to methacrylic acid and ethylene to acetic acid) and acid-catalyzed reactions (homogeneous liquid-phase hydration of olefins, biphasic polymerization of THF to

poly(tetramethylene glycol) and the gas-phase synthesis of ethyl acetate from ethylene and acetic) (Kozhevnikov 2007).

Nevertheless, in many processes using HPA catalysts, there are relevant difficulties concerning catalyst separation and recovery and reaction selectivity. In this perspective, the heterogenization of HPAs in membranes can offer important advantages in catalysis by the integration of the catalytic activity with the selective transport through the membranes.

Hydration of α -pinene to α -terpineol over molybdophosphoric acid entrapped in polyvinyl alcohol (PVA) membranes cross-linked with succinic acid, and molybdophosphoric acid encaged in zeolites and dispersed in polydimethylsiloxane (PDMS) membranes, have been reported in literature (Castanheiro et al. 2003). In both cases, the catalytic activity of the membranes is quite good in successive runs although a partial catalyst leaching was observed.

Catalytic membranes have been prepared by linking phosphotungstic acid on the surface of plasma-modified membranes made of polyvinylidene fluoride (PVDF). The PVDF membranes was modified by plasma treatments on the surface, in order to graft N-containing polar groups able to act as binding sites with phosphotungstic acid. The catalytic activity of the membranes has been evaluated in the aerobic degradation reaction of phenol in water (Fontananova et al. 2006). Higher phenol degradation rate was observed for the HPA heterogenized on PVDF membrane compared to homogeneous catalyst dissolved in solution. Moreover, the catalytic membranes have given proof of their complete stability under photooxidation condition and their good recycle.

In numerous literature studies, it has been reported that the HPAs can reduce the resistance to the proton transport in PEMFCs.

The reduction of the HPAs particles sizes and their good dispersion inside the polymeric matrix resulted to be key factors in order to have a positive effect on the proton conductivity because of the increase of the surface to volume ratio of the additives and the possibility to have a more efficient proton hopping (Ramani et al. 2005).

HPAs typically exist in hydrated phase with the degree of hydration varying from 6 to 30 molecules of water, depending on the temperature and the relative humidity (e.g., six molecules of water are present in the $\text{H}_3\text{PW}_{12}\text{O}_{40}$ structure up to 175–230 °C) (Mioč et al. 2005). In Keggin-type HPAs, hydrogen bonds exist between each acid proton and two water molecules, are also present between water molecules and the terminal oxygen atoms of the HPAs, and moreover, involving different Keggin units (Moffat 1986).

If the HPA sizes are in the order of a few nanometers and uniformly distributed in the proton exchange membrane, the water hydration molecules and/or dioxonium ions of the additive can be used to better interconnect the ionic cluster of the polymeric matrix providing a better pathway for proton hopping (Ramani et al. 2005).

Composite membranes with higher glass transition temperature (T_g) and higher stability of the proton conductivity at high temperature have been obtained by incorporation of 60 wt.% of three different HPAs ($\text{H}_3\text{PW}_{12}\text{O}_{40}$, $\text{H}_3\text{PMo}_{12}\text{O}_{40}$, $\text{Na}_2\text{HPW}_{12}\text{O}_{40}$) in SPEEK membranes with 70 %, 74 %, and 80 % degree of sulfonation (Zaidi et al. 2000).

Hybrid membranes prepared from sulfonated polyetherketone (SPEK), heteropoly acids, and an inorganic network of ZrO_2 or $\text{RSiO}_{3/2}$ have been also prepared obtaining a higher proton conductivity of the membranes (Ponce et al. 2003).

The HPAs have been also used to stabilize the proton conductivity of the Nafion membranes at elevated temperature and low relative humidity. For example, $\text{H}_3\text{PW}_{12}\text{O}_{40}$, also exchanged with larger cations such as Cs^+ , NH_4^+ , Rb^+ , and Ti^+ , has been heterogenized in Nafion membranes observing better proton conductivity (Ramani et al. 2005).

Tungstophosphoric acid, silicotungstic acid, and phosphomolybdic acid have been used as functional additives in composite membranes made of the sulfonated derivative of an amorphous-modified polyetheretherketone, called SPEEK-WC (Fontananova et al. 2010).

The embedding of the inorganic HPAs, in particular the $\text{H}_4\text{SiW}_{12}\text{O}_{40}$, in SPEEK-WC membranes, enhanced the proton conductivity

Heteropolyacid Composite Membranes,

Fig. 1 Schematic view of the interactions by hydrogen bonds between a heteropoly acid (the Keggin structure is represented) with the sulfonic group of a cation exchange membrane, the water hydration molecules, and dioxonium ions

because the HPAs improved the interconnection of the ionic clusters in the polymeric matrix providing a preferential pathway for proton hopping (Fig. 1).

Heteropolyacids

Ubavka B. Mioč

Faculty of Physical Chemistry, University of Belgrade, Belgrade, Republic of Serbia

The basic structural unit in heteropolyacids (HPAs) is the Keggin's cluster (find "Keggin's structure"). Groups are distributed in a three-dimensional lattice and are interconnected by hydrogen-bonded water molecules or some other proton species (OH^- , H_2O , H_3O^+ , H_5O_2^+) forming the secondary structure of Keggin's anion. Water molecules fill channels in solid HPAs, and next interactions, $\text{OH}^- \dots \text{H}_2\text{O}$, $\text{H}_2\text{O} \dots \text{H}_2\text{O}$ and $\text{H}_3\text{O}^+ \dots \text{H}_2\text{O}$, are identified.

Empirical $R_{O...O}$ distances, between 294 and 263 nm, correspond to weak and medium hydrogen bonds.

Three best-known acids have been investigated: $H_3PMo_{12}O_{40} \times 29H_2O$ (MoPA), $H_3PW_{12}O_{40} \times 29H_2O$ (WPA), and $H_4SiW_{12}O_{40} \times 30H_2O$ (WSiA). All three acids are isostructural. Among HPAs 12-tungstophosphoric acid hydrates, characterized by strong acidity, are classified into “superacids” (Okuhara et al. 2004). From mother solutions HPAs crystallize with high number of water molecules, 29–30, forming quasi liquid state. Acids are very sensitive to ambient conditions: relative humidity and temperature, and lose very easily water molecules and change to lower hydrates, Eq. 1 and Fig. 1. On the other hand, dehydrated acids are very hygroscopic.

Therefore it is interesting and necessary to see how these compounds change in process of calcination/dehydration and to determine structural phase transition and temperature regions of their stabilities, Fig. 2. Investigations have to be multidisciplinary and different physicochemical methods have to be used. Thermal analysis (TGA, DTA), XRPD, IR, and Raman spectroscopy are recommended for the beginning (Pope and Müller 1994; Mioč et al. 1990, 1994, 2005). Thanks to such investigations besides the phase transition to different crystal hydrates: –29, –21, –14, and –6 hydrates, dehydrated phase, WPA-0, at about 230 °C, was defined as cubic phase. It was postulated that Keggin’s anions of WPA-0 phase are stabilized by protons – “free protons.”

Heteropolyacids, Fig. 1 Schematic survey of different steps of hydration of HPAs

At higher temperatures, about 400 °C (the broad peak) was defined as T_g anomaly on DTA curves. It corresponds to exothermic transformation which is followed by the mass loss (TGA) corresponding to about 0.5–0.3 water molecules.

It was evident that these water molecules are formed from protons and few oxygen atoms from host lattice in endothermic process, which is simultaneous with water dehydration.

Nowadays, this water is called protonated (Janik et al. 2004). Metastable (D-phase–denuded phase) is stable up to 604 °C, for WPA, when structural phase transformation to phosphate tungsten

Heteropolyacids,

Fig. 2 DTA and TGA curves of WPA-29 in different temperature regions. Scanning rates were 1, 5, and 10 °C/min

DTA and TGA curves of 29-WPA at temperatures up to 1000 C

bronzes (PWB) happen (Mioč et al. 1994, 2005). All WPA phases were indexed and corresponding unit cell dimension calculated. Some of them for the first time: WPA-14 as triclinic. All phases from WPA-6 up to structural phase transformation are cubic. Phosphate tungsten bronzes (PWB) have also been obtained and defined for the first time using HPAs as precursor (Mioč et al. 1994). Fournier noted also the same large peak for WPA and identified it as a new Q phase.

He claims that a new Q phase is formed after the loss of “constitutional” water (Fournier et al. 1992).

These investigations have been followed by IR and Raman spectroscopic study in situ, in temperature range from temperature of liquid nitrogen -195 to 220 $^{\circ}C$, and with ^{18}O -labeled compounds. On the basis of the obtained spectra, few proton species were identified ($H_5O_2^+$, H_3O^+ , H_2O , and OH^- groups): terminal OH^- groups of

Keggin's anions at about 3,550; OH^- groups from water molecules, due to the most frequent interaction $\text{H}_2\text{O} \cdots \text{H}_2\text{O}$ at about 3,490; and OH bands belonging to $\text{H}_3\text{O}^+ \cdots \text{H}_2\text{O}$, the strongest interaction at about 3,292 and 3,225 and 3,140 cm^{-1} ; bands in the region 2,250–2,050 were assigned to ν_3 and/or ν_4 of H_3O^+ and water libration modes. Dioxonium ion was identified also, thanks to the band ν_4 at 1,720 and ν_2 at about 1,220 cm^{-1} . Special attention in the process of calcination/dehydration was paid to the intensity changes of bands $\nu_4(\text{H}_3\text{O}^+)$ at 1,720 and $\nu_2(\text{H}_2\text{O})$ at 1,610 cm^{-1} (Mioč et al. 1990, 1994, 2005).

Protonic entities and their dynamic equilibrium influence the host structure too. Identification of proton species and following of its dynamic equilibrium is also very important for understanding catalytic (formation of Brønsted acid centers) and conductive processes (defining charge carriers, conductivity dependence of temperature, frequency, and so on) as characteristics of these compounds.

Hexavalent Chromium Separation by Supported Liquid Membranes

Pietro Argurio

Department of Environmental and Chemical Engineering, University of Calabria, Arcavacata di Rende, Italy

The removal and/or recovery of heavy metals from industrial wastewater is a major topic of research. Chromium is a unique, toxic heavy metal released in aqueous environment in both +3 and +6 oxidation states. Hexavalent chromium (Cr(VI)) receives particular attention because of its mutagenic, teratogenic and carcinogenic properties. Cr(VI) exists as anionic species, such as HCrO_4^- , $\text{Cr}_2\text{O}_7^{2-}$, and CrO_4^{2-} , which are highly mobile on subsurface environment (Kumbasar 2008). These anionic species are bioaccumulative, and their oxidizing potentials make them highly toxic to biological systems. The major industries that contribute to water pollution by chromium are mining, leather tanning, textile dyeing, electroplating, metal finishing, and corrosion inhibition (Rajasimman and Karthic 2010).

The World Health Organization recommends the toxic limits of Cr(VI) in wastewaters at the level of 0.005 mg/L. Many countries have regulations of the maximum permissible concentration of Cr(VI) in natural or drinking water which typical tolerance limit for discharge into inland surface waters is 0.1 mg/L and in potable water is 0.05 mg/L. Usually Cr(VI) concentrations in industrial wastewaters range from 0.5 to 270,000 mg/L. Then chromium-bearing wastewaters must be discharged into aquatic environments or onto land after appropriate treatments to drastically reduce Cr(VI) content.

The methodologies for Cr(VI) recovery, from industrial wastewater, range from ion exchange to solvent extraction, non-dispersive solvent extraction, precipitation, and adsorption. Solvent extraction has been widely used for the removal and/or recovery of chromium in hydrometallurgy since this technique allows the Cr ions recovery, but it involves high capital and operating costs due to

large inventory of solvent, especially in the case of dilute solutions. Conventionally the treatment chromium-bearing wastewaters consists of the reduction of Cr(VI) to Cr(III) with an adequate chemical-reducing agent. Cr(III) is then easily precipitated by the addition of an alkali compound (generally calcium hydroxide) to the liquid effluent. The main drawback of this method is the production of a large amount of sludge-containing chromium often in high concentration, which disposal/treatment is a very costly affair and it is not eco-friendly.

Supported liquid membrane (SLM) process offers a technology with a low solvent/extractant consumption since it involves in a single stage the extraction and stripping processes, which are generally performed in two separate steps in conventional solvent extraction. SLM consists of a LM phase, impregnated in the pores of a thin hydrophobic microfiltration membrane, kept there by capillary forces. It combines the typical advantages of liquid membrane with the mechanical resistance of solid membranes. The transport across a SLM is mediated by a mobile extractant (carrier) which binds very selectively the target component in the donor phase (feed), transporting it into the acceptor phase (strip), resulting in the so-called facilitated transport (Molinari et al. 2009a, b). The selection of an appropriate carrier provides higher selectivity and enrichment factor as compared to the other separation methodologies.

Despite of their advantages with respect to the traditional separation techniques, SLM is not widely applied in treatment of chromium-bearing wastewaters. Cr(VI) compounds could be removed from dilute aqueous solutions by using trioctylphosphine oxide (TOPO), Alamine 336, tri-n-octylamine (TOA), and tributyl phosphine (TBP) as ionic carrier.

The extraction of HCrO_4^- with TOPO from acidic solutions could be expressed by the following equation (Kumbasar 2009; Hasan et al. 2009):

Hexavalent Chromium Separation by Supported Liquid Membranes, Fig. 1 Schematics of separation mechanism through liquid membrane

The so-formed complex diffuses through the membrane toward the stripping basic solution where the de-complexation reaction takes place and HCrO_4^- and H^+ ions are released. The so-regenerated carrier molecule diffuses back to the feed and the transport cycle begins again (Fig. 1). This transport mechanism is the so-called facilitated coupled co-transport, typical when a basic carrier like amines or phosphates is used to transport negatively charged species (in this case HCrO_4^-) and usually H^+ as counterion across the membrane in the same direction (Fig. 1).

Cr(VI) complexes can be efficiently removed from acidic chloride aqueous solutions by facilitated transport with TOA into a basic (NaOH 0.1 M) acceptor phase (Kozłowski and Walkowiak 2002). In agreement with the transport mechanism that is similar to that one previously reported for TOPO, the permeability coefficient and then initial flux values decrease linearly by increasing the feed pH. Cr(VI) concentration can be successfully reduced in the feed phase from 1.0 to 0.0028 mg/L, thus respecting the World Health Organization's recommendations.

High Free Volume Polymer

Peter M. Budd

Organic Materials Innovation Centre, School of Chemistry, University of Manchester, Manchester, UK

Free volume is the unoccupied space between molecules. The concept of free volume is used to explain molecular motion in liquids and solids. In a liquid or rubber, free volume increases with increasing temperature. A flexible polymer will flow or behave as a rubber at temperatures at which there is sufficient free volume for large-scale movements of polymer segments but will behave as a glass when the temperature is reduced to the point where there is not enough free volume for such movements.

Different assumptions may be made about what constitutes “occupied” and what constitutes “free” volume in a material. Thus, in different contexts, different values may be quoted for the amount of free volume in a polymer. In membrane science, it is common to define fractional free volume as

$$f_v = \frac{V - 1.3V_w}{V}$$

where V is the specific volume (reciprocal of density) and V_w is the specific van der Waals volume, which for many polymers may be estimated using group contribution methods. The factor 1.3 takes account of the fact that molecules cannot completely fill space even in a perfectly ordered crystal at absolute zero and is an average value for crystalline materials. By this definition, most glassy polymers have $f_v < 0.2$. Some glassy polymers, however, have much higher fractional free volumes and consequently exhibit high permeabilities to gases and vapors (Budd and McKeown 2010; Yampolskii 2012; Pinnau and Toy 1996; Starannikova et al. 2008; Thomas et al. 2009). The structures of some polymers with exceptionally high free volume are shown in Fig. 1.

A common feature of high free volume polymers is that they have relatively inflexible, twisted backbones, which cannot change conformation in order to fill space efficiently. In substituted polyacetylenes such as PTMSP, the bulky side group inhibits rotation about single bonds in the backbone and forces the backbone into a twisted shape. In perfluoropolymers such as Teflon AF2400, neighboring dioxolane rings cannot easily rotate past each other. In substituted polynorbornenes prepared by addition polymerization, such as PTMSN, ring structures and bulky side groups restrict rotation about backbone bonds. The ultimate extension of this idea is found in polymers of intrinsic microporosity, such as PIM-1, which have no single bonds in the backbone about which rotation can occur but which incorporate sites of contortion (the spiro centers in PIM-1) to force the backbone to twist and turn.

The polymers shown in Fig. 1 are soluble and can readily be processed from solution to form membranes. However, there are other high free volume polymers which cannot be prepared in soluble form. Sometimes, it is possible to form a membrane from a soluble precursor and subsequently convert it to the desired structure through chemical or thermal treatment. For example,

**PTMSP**
 $f_V = 0.33$ (Hofmann et al. 2002)
**Teflon AF2400** ($x=0.87$, $y=0.13$)
 $f_V = 0.33$ (Pinnau and Toy 1996)
**PTMSN**
 $f_V = 0.28$

(Starannikova et al. 2008)

**PIM-1**
 $f_V = 0.24$ – 0.26 (Thomas et al. 2009)

High Free Volume Polymer, Fig. 1 Molecular structures and fractional free volumes of poly(1-trimethylsilyl-1-propyne) (PTMSP), a copolymer of 2,2-bis(trifluoromethyl)-4,5-difluoro-1,3-dioxole and tetrafluoroethylene (Teflon AF2400), addition-type poly(trimethylsilyl norbornene)

(PTMSN), and a polymer of intrinsic microporosity prepared from 5,5',6,6'-tetrahydroxy-3,3',3'-tetramethyl-1,1'-spirobisindane and 1,4-dicyanotetrafluorobenzene (PIM-1)

polybenzoxazole structures can be prepared by thermal rearrangement from aromatic hydroxyl-containing polyimides (Park et al. 2007).

The permeation of gases and vapors through a polymer depends not only on the amount of free volume but also on the size, distribution, and connectivity of free volume elements. Computer simulation is useful for visualizing the free volume distribution in amorphous polymers (Hofmann et al. 2002). A number of experimental techniques, notably positron annihilation lifetime spectroscopy (PALS), have been employed to obtain information about the size and distribution of free volume elements. In a high free volume polymer, there may be sufficient connectivity between free volume elements for the polymer to behave like a molecular sieve or microporous

material (pore size <2 nm) (Rutherford 2001), in which case the apparent micropore distribution can be determined from gas adsorption studies (McKeown and Budd 2010).

High Selective Carbon Membranes

Miki Yoshimune

Research Institute for Chemical Process
Technology, National Institute of Advanced
Industrial Science and Technology (AIST),
Tsukuba, Japan

In general, carbon membranes prepared under appropriate conditions show higher selectivities in gas separations than do conventional polymer membranes (Ismail and David 2001; Saufi and Ismail 2004; Kita 2006; Ismail and Li 2008; Williams and Koros 2008; Yoshimune and Haraya 2011). Examples of O_2/N_2 separation performances of carbon membranes, taken from literature sources, are plotted in Fig. 1, which also shows the upper limits for polymer membranes (Kita et al. 1997; Suda and Haraya 1997; Shiflett and Foley 2000; Ghosal and Koros 2000; Kim et al. 2004, 2005; Shao et al. 2004; Yoshimune et al. 2005; Xiao et al. 2005a, b; Robeson 2008). The carbon membranes were prepared from various precursors, including various aromatic polyimides (Kapton, Matrimid, etc.), polyfurfuryl

alcohol (PFA), a polypyrrolone, and poly(2,6-dimethyl-1,4-phenylene oxide) (PPO). Results for O_2/N_2 selectivity and O_2 permeability are sometimes used as benchmarks for characterizing the properties of membranes as a function of synthesis variables. It can be clearly seen that most carbon membranes have O_2/N_2 selectivities that are roughly three times higher than the upper limit for polymer membranes when the selectivities are compared at the same O_2 permeability. Previous reports have shown that carbon membranes have considerable promise for commercial applications, not only in O_2/N_2 separation but also in hydrogen purification and the separation of CO_2/CH_4 , CO_2/N_2 , or propene/propane mixtures, which are all processes in which conventional polymer membranes do not perform adequately.

Optimal conditions for the production of carbon membranes vary according to the nature of the precursor polymers and their morphologies, because the various polymers show different thermal decomposition behaviors. Control of the conditions for pyrolysis of the precursor polymer, as discussed below, is the most important factor in increasing the gas selectivity of the resulting carbon membrane, because the nature of the pyrolysis process has a considerable effect on the pore structures of the membrane.

Pyrolysis Temperature

The pyrolysis temperature is generally chosen to be above the decomposition temperature of the polymer, but below its graphitization temperature (500–1000 °C). As a general rule, an increase in the pyrolysis temperature reduces the permeability of the resulting carbon membrane but increases its selectivity. High pyrolysis temperatures produce increased crystallinity and lower average interplanar spacings in carbon membranes, resulting in smaller micropores and sharper pore-size distributions. This behavior certainly depends on the physical properties of the polymer, so that a suitable carbonization temperature needs to be chosen individually for a particular polymer precursor to achieve optimal performance in gas separations.

High Selective Carbon Membranes,

Fig. 1 Comparison of the oxygen permeabilities and selectivities of various carbon membranes with the upper limit for polymer membranes ([a] Suda and Haraya 1997, [b] Xiao et al. 2005a, [c] Kim et al. 2005, [d] Xiao et al. 2005b, [e] Ghosal and Koros 2000, [f] Kim et al. 2004, [g] Shao et al. 2004, [h] Shiftlett and Foley 2000, [i] Kita et al. 1997, [j] Yoshimune et al. 2005, [k] Robeson 2008)

Thermal Soak Time

The thermal soak time can have varied effects on the performance of the final membrane. Changing the thermal soak time, particularly at the final pyrolysis temperature, can be used effectively to fine-tune the permeation properties of a carbon membrane. A prolonged thermal soak time increases the selectivity of carbon membranes but decreases their permeability.

Heating Rate

The heating rate determines the rate of evolution of volatile components from a polymeric membrane during pyrolysis and, consequently, affects the nature of the pores that are formed in the resulting carbon membrane. Lower heating rates (5 °C/min or less) favor the formation of small pores and increase the crystallinity of the resulting carbon, thereby producing carbon membranes with increased selectivities. From the practical

standpoint, however, an optimal heating rate that is not too low should be chosen, because low heating rates increase the costs and time involved in producing carbon membranes.

Another method for tuning the gas selectivities of carbon membranes is the production of mixed-matrix membranes (Yoshimune and Haraya 2011). Mixed-matrix carbon membranes are defined as products of the pyrolysis of membranes consisting of a continuous polymer matrix containing nano-sized inorganic particles dispersed throughout the polymer. Metal ions or particles, silica particles, zeolites, or carbons are normally used as inorganic particles to improve the properties of the resulting membranes. Such nano-sized particles increase the polarity of the membranes, form interlayer spaces, or have an affinity toward target gases.

Figure 2 shows the hydrogen permeability and selectivity of several types of mixed-matrix carbon membranes (Park et al. 2004; Yoda et al. 2004; Park and Lee 2005; Liu et al. 2006; Yoshimune et al. 2006; Grainger and Hägg 2007). Some of the mixed-matrix carbon membranes

High Selective Carbon Membranes,

Fig. 2 Comparison of the hydrogen permeabilities and selectivities of various mixed-matrix carbon membranes with the upper limits for polymer membranes ([a] Suda and Haraya 1997, [k] Robeson 2008, [l] Grainger and Hägg 2007, [m] Yoda et al. 2004, [n] Yoshimune et al. 2006, [o] Park et al. 2004, [p] Park and Lee 2005, [q] Liu et al. 2006)

exhibit significantly superior performances in comparison to that of the Kapton-derived carbon membrane, which is shown here as the boundary for pure-carbon membranes. This technique can help to improve the trade-off between the permeability and the selectivity of carbon membranes, as well as provide novel functionalities in membrane reactors.

High selectivity by carbon membranes is generally observed in the case of dense membranes in forms such as flat sheets or hollow fibers. For commercial applications, it is necessary to fabricate membranes into modules that have both a high selectivity and a high permeability. Thinner separation layers, such as asymmetric hollow fibers, in combination with adequate mechanical strength are desirable; however, carbon membranes are brittle in handling, and even a small number of pinholes can ruin their gas selectivity. This hinders the production of carbon membranes on an industrial scale. Although carbon membranes have considerable potential for use, not only in gas and vapor separations but also as membrane reactors, further investigations are needed before they can be used commercially.

Higher (C3+) Hydrocarbon Removal

Arnaud Baudot

Physics and Analysis Division, IFP Energies
Nouvelles, Solaize, France

Rubbery polymer membrane materials have the ability to permeate preferentially condensable vapors. Rubbery membranes were found to be very profitable for the recovery of high-value monomer in petrochemical plants' purge gases (Table 1). In the case of large polymerization facilities, the value of purge monomers can reach amounts up to two million USD/year.

Higher (C3+) Hydrocarbon Removal, Table 1 Membrane-based olefin recovery from polymer resin degassing vent (MTR Inc. membrane modules) Baker and Jacobs 1996; Baker et al. 2000

Application	Feed composition	Olefin flow rate recovered (recovery yield)
LLDPE/HDPE reactor purge	Butene 36 % Ethylene 41 % Ethane 1 % Nitrogen 21 % Hydrogen 1 %	C2 = 145 kg/h (88 %) nC4 = 142 kg/h (98 %)
HDPE resin degassing	1-butene 57 % CO ₂ /O ₂ 2 % Nitrogen 40 % Water 1 %	iC4 = 1160 kg/h (97 %)
Polypropylene resin degassing	Propylene 14 % Propane 0.3 % Nitrogen 84.4 % Hydrogen 1 % Water 0.3 %	C3 = 500 kg/h (91 %)

Highly Permeable Polyimides

Mariolino Carta

School of Chemistry, The University of Edinburgh, Edinburgh, Scotland, UK

Polyimides are polymers produced by cycloimidization (formation of an imide linkage) between di-anhydrides and diamines via step-growth polymerization (Koros and Fleming 1993; Ghosh and Mittal 1996). Among other useful applications such as materials for electronics, coatings, foam, and fibers, because of their excellent solubility in common low boiling point solvents, thermal stability, and physical properties, they have been extensively studied as gas separation membranes. A typical limitation for their use in this field is due to the fact that they often exhibit high selectivity but low permeability for important gas pairs such as O₂ and CO₂, usually far below 100 Barrer (1 Barrer = 10⁻¹⁰ cm³(STP) cm cm⁻² s⁻¹ cmHg⁻¹). The low permeability is strongly related with the lack of fractional free volume of the material (FFV) because of the free rotation around the imide linkage that allows the polymer to pack densely, limiting the mass transport. Initial successes in enhancing the permeability by increasing the FFV have been achieved with the use of 4, 4'-(hexafluoroisopropylidene)diphthalic anhydride (6FDA), which is now one of the

most common monomers for the formation of high-performance polyimides (Fig. 1), and 2,3,5,6-tetramethyl-1, 4-phenylenediamine (4MPDA). The hindrance of the four methyl groups of the di-aniline restricts the rotation around the imide linkage allowing the synthesis of more porous (so less dense) polyimides. The higher porosity facilitates the mass transport of the gases through the pores of the membrane with consequent increase of the permeability (molecular sieving effect), typically over 100 Barrer for O₂ and 400 Barrer for CO₂ with selectivity $\alpha_{\text{O}_2/\text{N}_2} = 3.5$ and $\alpha_{\text{H}_2/\text{N}_2} = 16.6$ (Lin et al. 2000).

A different method to increase the FFV is represented by the formation of hyperbranched polyimides. In this case a triamine monomer, such as 1,3,5-tris(4-aminophenoxy)benzene (TAPOB), is reacted with different di-anhydrides to obtain a highly branched structure (Tsai et al. 2003) (Fig. 2). The polyimides obtained with this technique are insoluble so, to be used as membrane for gas separation, they must be embedded in a support. Typically, it can be prepared by the dispersion of the polyimide with colloidal silica by sol-gel processes, to form a composite material. The most remarkable characteristic of this hyperbranched polymer is that they can be made out of a large variety of A₃ + B₂ terminal groups so that the synthesis can afford different multifunctional polymers.

Following the idea of restricting the rotation around the imide link, the concept of *polymers of intrinsic microporosity* (PIMs), which is based on the polymerization of monomers that possess a *site of contortion*, was applied to the synthesis of polyimides. In this case, di-anhydrides and/or di-anilines such as the spirobisindane **A** or the ethanoanthracene **B** (as shown in Fig. 3) are employed. The *site of contortion* is represented

Highly Permeable Polyimides, Fig. 1 6FDA + 4MPDA-based polyimide (Lin et al. 2000)

Highly Permeable Polyimides, Fig. 2 Hyperbranched polyimides (Tsai et al. 2003)

Highly Permeable Polyimides, Fig. 3 Highly permeable polyimides of intrinsic microporosity (Rogan et al. 2014)

by the central quaternary carbon in case of **A** or the methylene bridge for **B** (Rogan et al. 2014). Although there is still free rotation around the imide linkage, the big hindrance of the bulky substituent, combined with the reduced flexibility given by the *site of contortion*, allows the formation of high FFV polymers that cannot pack space efficiently in the solid state, leaving interconnected pores of nano-/microdimension

(for this reason they are called *polymers of intrinsic microporosity*).

Studies on this class of polymers demonstrate that the systematic increase of the rigidity of the structural backbone favors the molecular sieving effect of the material, enhancing both permeability and selectivity for various gas pairs. The resulting PIM-polyimides (PIM-PIs) possess high molecular mass and elevated microporosity,

with BET surface areas in the range of 600–700 m²g^{−1}. These features, associated with the high solubility in common organic solvents, allow the preparation of robust thin-film membranes with excellent performance toward important commercial gas pairs, such as O₂/N₂, H₂/N₂, and CO₂/CH₄, with exceptional permeabilities (over 1000 Barrer for O₂ and over 7000 Barrer for CO₂) accompanied by good selectivities $\alpha_{\text{O}_2/\text{N}_2} = 3.5$, $\alpha_{\text{H}_2/\text{N}_2} = 11.5$, and $\alpha_{\text{CO}_2/\text{CH}_4} = 16.1$. Remarkably, all data points lie above the Robeson upper bounds. With the appropriate choice of the monomers of both di-anhydrides and di-anilines, it is possible to tune the physical properties of these highly permeable polyimides to improve them even further.

High-Pressure Electrolysis

César Valderrama

Department of Chemical Engineering, Universitat Politècnica de Catalunya-Barcelona Tech (UPC), Barcelona, Catalonia, Spain

High-pressure electrolysis (also called high-pressure electrolysis HPE) is the water electrolysis performed at pressures higher than ambient in which electrical energy is the driving force of the water decomposition to produce oxygen (O₂) and hydrogen (H₂). The core of an electrolysis unit is an electrochemical cell, which is filled with pure

water and has two electrodes connected with an external power supply. Electric current causes positively charged hydrogen ions to migrate to the negatively charged cathode, where a reduction takes place in order to form hydrogen atoms. The atoms formed then combine to form gaseous hydrogen molecules (Eq. 1). On the other hand, oxygen is formed at the other electrode (the positively charged anode) (Eq. 2). The amount of gases produced per unit time is directly related to the current that passes through the electrochemical cell (Wendt and Kreysa 1999).

Oxygen and hydrogen gas can be generated at noble metal electrodes by the electrolysis of water: Positive electrode (anode):

Negative electrode (cathode):

In a differential pressure configuration, only the cathode (hydrogen) side is under pressure, and this can eliminate the hazards related to handling pressurized oxygen. The high-pressure operation of an electrolyser brings the advantage of delivering hydrogen at a high pressure (sometimes called electrochemical compression) for the end user, thus requiring less energy to further compress and store the hydrogen. It also diminishes the volume of the gaseous phase at the electrodes thus significantly improving product gas removal which follows Fick's law of diffusion (Carmo et al. 2013).

A number of advantages can be gained from operating an electrolyser at high pressure; on the one hand, specific power consumption is reduced, then the cost of gas compressors is reduced or eliminated by delivery of gas pressure, and finally, the size of electrolysis cells is reduced. Though the reversible cell voltage increases theoretically with pressure, the overvoltage is reduced by higher operating pressure and decreased gas volume, and a small overall reduction in the cell voltage is usually found (Zoulias et al. 2004).

Types of Electrolysers

The electrolyser unit consists in the simplest principle of two electrodes separated by an electrolyte. The role of the electrolyte is to close the electrical circuit by allowing ions (but not electrons) to move between the electrodes. Moreover it keeps the produced gases separated. Three common types of electrolysers are used: (i) alkaline electrolysers, (ii) polymer electrolyte membrane (PEM) electrolysers, and (iii) solid oxide electrolysis cells (SOECs).

Alkaline electrolysers (AEC) represent a very mature technology that is the current standard for large-scale electrolysis. The anode and cathode materials in these systems are typically made of nickel-plated steel and steel, respectively. The electrolyte in these systems is a liquid based on a highly caustic KOH solution. The ionic charge carrier is the hydroxyl ion, OH⁻, and a membrane porous to hydroxyl ions, but not to H₂, and O₂ provides gas separation. Key advantages of this technology include its maturity and its durability. Key disadvantages are its use of a highly caustic electrolyte and its inability to produce hydrogen at high pressures (Jensen et al. 2008). This inability to produce high-pressure hydrogen for storage results in the added need for an external compressor, which adds cost and complexity to the system.

Water electrolysis by solid oxide electrolysis cells (SOECs) is principally performed at temperatures in between 700 °C and 1000 °C (see entry ► [High-Temperature Electrolysis](#)) due to the H₂ electrolysis reaction which becomes increasingly endothermic with temperature and the ohmic losses in SOECs which decrease with increasing temperature. The high temperature allows hydrogen production with significantly reduced electrical energy demand (Larminie and Dicks 2003).

In an acidic polymer electrolyte membrane (PEM) electrolysis cell, water splitting is performed according to the reactions shown by (Eqs. 1 and 2). Protons are formed at the anode under water consumption, where the oxygen evolution reaction (OER) takes place. The protons migrate through the solid polymer electrolyte (SPE) membrane to the cathode, where they are reduced into hydrogen. The polymer electrolyte

membrane (Nafion[®], fumapem[®]) provides high proton conductivity, low gas crossover, compact system design, and high-pressure operation (Carmo et al. 2013).

The reinforcement of the cells with metallic support on the anode side allows the generation of hydrogen at high pressures (up to 160 bar commercial units) (Badwal et al. 2013). The energy penalty for generating hydrogen at higher pressures is very small, that is, an order of magnitude increase in hydrogen pressure requires only ~30 mV per cell increase in voltage (as shown by Nernst equation).

PEM electrolysis cells achieve high current densities already at low operational temperatures from 20 °C to 100 °C. PEM electrolysers are not utilized in market applications to the same extent as alkaline ones due to the high investment costs. One of the most important components of such a unit is a separating membrane that allows the passage of ions, or electrons and not oxygen, or hydrogen atoms. This membrane allows the gases to be kept separate in order to avoid the risk of an explosive mixture being formed in the electrolysis unit. The pressure increase minimizes the expansion and dehydration of the membrane, preserving the integrity of the catalytic layer (Grigorev et al. 2001). The membrane technology enables safe differential pressure operation, which in turn allows the electrolysis unit to be operated in a load-following mode with 100 % turndown capability, which is very attractive for renewable energy applications.

The electrolyser utilizes pure water as the circulating fluid, which results in a simpler balance of plant. The differential pressure also results in the ability to operate the oxygen-water fluid loop at ambient pressure, which has significant safety advantages as well as use of plastic tubing rather than expensive high-pressure piping.

The one disadvantage is the acidic environment within the membrane, which limits the catalysts to noble metal oxides and requires semiprecious metals in the oxygen flow fields. The ion exchange membrane is also more sensitive to impurities than the liquid electrolyte, since cations can bind to the proton-conducting sites, reducing conductivity (Zoulias et al. 2004).

²Singapore Membrane Technology Centre, Nanyang Environment and Water Research Institute, Nanyang Technological University, Singapore, Singapore

Introduction

Seawater desalination to convert seawater to potable water by reverse osmosis (RO) membranes has become a pivotal technology to meet the increasing water demand. The RO membrane has a unique property that allows passage of water with little hindrance while presenting a

virtually impermeable barrier to salts and other components. Over the years, it has evolved from the first-generation asymmetric cellulose acetate (CA) membrane to the current generation thin film composite (TFC) membranes with better salt retention and higher water permeability, which has significantly improved the water quality and reduced the energy consumption and costs of seawater desalination.

Structure of TFC RO Membrane and Separation Mechanism

TFC RO membrane, prepared using interfacial polymerization technique, is composed of an active skin layer (thickness ~200 nm and pore size of <0.1 nm) commonly made from cross-linked aromatic polyamides, a polysulfone porous support layer (thickness ~50 µm), and a polyester nonwoven fabric substrate (thickness ~100 µm), as shown in Fig. 1 (Kurihara and Tomioka 2010; Uemura et al. 2012).

The active layer determines the separation properties, whereas both the support layer and substrate merely provide mechanical support for the active layer to withstand high-operating pressures of up to 7 MPa. The physicochemical properties associated with the separation function are characterized by pore size, surface morphology or roughness, surface charge, and hydrophobicity (Bellona et al. 2004). Retention of compounds is based on solute-membrane interaction mechanisms, namely, steric hindrance, electrostatic repulsion for charged solutes, and hydrophobic-hydrophobic and dipole-dipole interactions. The transport mechanism for RO membranes can be described by the widely accepted solution-diffusion model (Wijmans and Baker 1995).

Challenges for RO Membrane Desalination

The commercially available TFC RO membranes have excellent salt retention properties, typically greater than 99.5 % (Baker 2004). However, boron removal, which is usually less than 95 %, is a major challenge to RO membranes to meet the recommended value of below 0.5 mg/L in drinking water by the World Health Organization (Jonsson and Macedonio 2010; Misdan et al. 2012). Boron exists naturally in seawater

High-Rejection Seawater Reverse Osmosis Membrane,

Fig. 1 Structure of composite RO membrane (Uemura et al. 2012)

(pH 7–8) in the form of uncharged boric acid with pKa value of 9.2 and at concentration of ~ 5 mg/L. Below pH 9, the non-hydrated boric acid is poorly rejected due to the lack of electric double layer repulsive force between the negatively charged membrane surface and boric acid. Current practice for boron removal in seawater desalination is either to install a second pass RO or ion exchange column to further purify the water or to increase the pH to above 9 so that the membrane can easily reject the hydrated boric acid. The latter is least preferred as it can promote membrane scaling by hardness in the water.

Another concern is the incomplete retention of trace organic micro-pollutants such as endocrine-disrupting compounds, pesticides, pharmaceutically active compounds, etc. (Bellona et al. 2004). In general, due to the nature of the membrane, charged/hydrophilic molecules have better retention than uncharged/hydrophobic molecules. However, predictive models to account for the organic solute transport through the membrane are still lacking.

In addition, true retention is an intrinsic property of the membrane, though the observed retention is strongly influenced by the process parameters such as operating pressure, temperature, pH, and membrane fouling. For instance, when a membrane is fouled, the solutes no longer freely move in the concentration polarization boundary layer, instead need to diffuse through the tortuous paths in the fouling layer. Consequently, the hindered back-diffusion effect causes greater accumulation of solutes at the membrane

wall, thus resulting in the increase of solute passage (Fane et al. 2009). Hence, a high-retention membrane needs to possess good antifouling properties to ensure consistent performance in long-term operation.

Future Direction

Incorporation of nano-materials and biomaterials into the active layer is seen to be the innovative way to produce the next generation of high-permeability and high-retention seawater RO membranes, i.e., nanocomposite or biomimetic membranes (Matsuura and Fane 2013). In addition, a thorough understanding on the molecular structures of membrane and its interaction with solutes via molecular simulation is necessary to allow better manipulation of surface properties such as the extent of cross-linking, chain-packing density, and chain stiffness in order to enhance the performance of RO membranes.

High-Temperature Electrolysis

César Valderrama

Department of Chemical Engineering, Universitat Politècnica de Catalunya-Barcelona Tech (UPC), Barcelona, Catalonia, Spain

High-temperature electrolysis (also called steam electrolysis) is the water electrolysis at temperatures that ranged between 700 and 1,000 °C in which electrical energy is the driving force of water splitting to produce oxygen (O₂) and hydrogen (H₂). The core of an electrolysis unit is an electrochemical cell, which is filled with pure water and has two electrodes connected with an external power supply. At a certain voltage, which is called critical voltage, between both electrodes, the electrodes start to produce hydrogen gas at the negatively biased electrode (Eq. 1) and oxygen gas at the positively biased electrode (Eq. 2). The amount of gases produced per unit time is directly related to the current that passes through the electrochemical cell (Wendt and Kreysa 1999).

Oxygen and hydrogen gas can be generated at noble metal electrodes by the electrolysis of water: positive electrode (anode):

negative electrode (cathode):

From the thermodynamic viewpoint of water decomposition, it is more advantageous to electrolyze water at high temperature (800–1,000 °C) because the energy is supplied in mixed form of electricity and heat. The main advantage is that a substantial part of the energy needed for the electrolysis process is added as heat, which is much cheaper than electric energy. In addition, the high temperature accelerates the reaction kinetics, reducing the energy loss due to electrode polarization, thus increasing the overall system efficiency (Zoulias et al. 2004).

The minimum necessary cell voltage for the start-up of electrolysis, E_{cell}^0 , is given under standard conditions (P, T constant) by the following equation (Allebrod 2013):

$$E_{cell}^0 = \frac{-\Delta G^0}{nF}$$

where ΔG^0 is the change in the Gibbs free energy under standard conditions, n is the number of electrons transferred, and F is the Faraday constant. The overall water electrolysis cell reaction, E^0 (25 °C), is 1.23 V, the Gibbs free energy change of the reaction is +237.2 kJ/mol, and the standard reaction enthalpy is $\Delta H^0 = 285.8$ (kJ/mol). The water splitting is an endothermic reaction, and the term ΔG decreases with increasing temperature (Zeng and Zhang 2010).

Thermodynamic conditions of high-temperature electrolysis are more favorable in the sense that the molar Gibbs energy of the reaction (ΔG) drops from ~1.23 V (237 kJ/mol) at ambient temperature to ~0.95 V at 900 °C (183 kJ/mol), while the molar enthalpy of the reaction (ΔH) remains essentially unchanged ($\Delta H \sim 1.3$ V or 249 kJ/mol at 900 °C) (Larminie and Dicks 2003). A significant part of the energy required for an ideal (loss free) high-temperature electrolysis can thus be provided by heat. Thus, these systems can utilize waste heat from nuclear (especially fast breeder reactors), chemical, and

High-Temperature Electrolysis, Fig. 1 A schematic of solid oxide electrolysis cell (SOEC) for high-pressure electrolysis (Brisse et al. 2008)

coal- or natural gas-fired power plants and reduce the electric power requirements. Alternatively, the heat may come from solar concentrators, where high temperatures (above 800 °C) can easily be achieved.

Steam electrolysis or vapor electrolysis is performed using solid oxide electrolysis cell (SOEC) as shown in Fig. 1. This may be viewed in simple terms as the reverse operation of a solid oxide fuel cell.

The stream passes through the cathode side of the solid electrolyte where hydrogen ions are reduced to hydrogen, releasing oxide ions in the process (Eq. 3). The oxide ions then migrate through the electrolyte to the anode where they combine to form oxygen molecules (Eq. 4), releasing an electron current following back to the power source (Zeng and Zhang 2010).

The reactions on two electrodes are:

There are a number of materials that are used for the fabrication of electrolyzers that operate above 500 °C. The electrolyte is typically an oxide

ceramic and conducts either oxide ions or protons. Such systems are typically known as solid oxide electrolysis cells (SOEC). Material choice for the electrodes and operating temperature is essentially defined by the composition and type of the electrolyte material used with all other components being matched to the electrolyte. The conductivity of the electrolyte is a key parameter as it is a large contributor to cell losses and defines the design and operating temperature regime of the electrolysis cell.

The most widely studied high-temperature electrolyzers are based on O²⁻-conducting ceramics such as fully or partially stabilized (with Y₂O₃, Sc₂O₃) zirconia (referred to as YSZ or ScSZ). The advantages of these electrolyzers are that they can be incorporated with low-grade waste heat from chemical or power plants or solar thermal energy to reduce the electrical power input and increase efficiency; however, severe limitations on construction materials; significant problems with system design, materials' degradation, and lifetimes; hydrogen production on the anode side of the cell leading to complex system design; slow start-up and shut-down; and limited thermal cycling capability are disadvantages of these conducting systems (Badwal et al. 2013).

Apart from O²⁻-conducting electrolytes, several proton-conducting systems have been studied for the electrolysis of steam. In these systems, pure hydrogen is produced on the cathode side of the electrolysis cell with the oxygen being produced in the anode chamber where steam is present. Proton conduction in perovskite-structured SrCeO₃, where Ce is partially (5–10 %) substituted by Y, Yb, Mg, or Sc, was first developed and used for steam electrolysis in the 1980s. Following this early work, a number of other materials (based on BaCeO₃, CaZrO₃, SrZrO₃, and BaZrO₃) have been investigated, and their performance in steam electrolysis cells evaluated. Hydrogen is produced on the cathode side that simplifies system design, but in addition to the disadvantages of O²⁻-conducting systems, very few electrolytes offer good proton conductivity and stability in the operating regime (Badwal et al. 2013).

Hydrogen production via steam electrolysis may involve less electrical energy consumption than conventional low-temperature water electrolysis, reflecting the improved thermodynamic and kinetic operating conditions at elevated temperatures. For an average current density of $7,000 \text{ A}\cdot\text{m}^{-2}$ and an inlet steam temperature of $1,023 \text{ K}$, the predicted electrical energy consumption of the stack is around 3 kWh per normal m^3 of hydrogen, which is significantly smaller than 4.5 kWh of low-temperature alkaline water electrolysis cells commercially available today (Zeng and Zhang 2010). However, this result does not include the heating energy circulation and loss. Furthermore, construction materials, safety issues, and strict temperature control have to be addressed as well. Typical high-temperature electrolyser achieves 92 % electrical efficiency, while low-temperature electrolyzers can reach at most 85 % efficiency (Zoulias et al. 2004). Despite this high efficiency with respect to electricity, the high-temperature system still produces hydrogen at about four times the cost of the steam reforming hydrogen.

Intermediate-temperature electrolysis: A number of proton and O_2 —conductors are available for potential use as the solid electrolyte for water electrolysis in the 100 – 500°C temperature range. The perfluorosulfonic acid polymer membrane-based electrolyzers (PEM) are generally not operated above 90°C due to a reduction in proton conductivity caused by its dehydration. Approaches used to increase the operating temperature range of polymer membranes (fuel cells and electrolysis cells) include the use of Polybenzimidazole (PBI)/acid complex membranes, hybrid membranes consisting of polymers, and proton-conducting oxides and composite membranes consisting of ceramic particles (SiO_2 , TiO_2 , etc.) impregnated proton-conducting membranes. Mainly, SiO_2 - or TiO_2 -impregnated perfluorinated polymer-based composite membranes (cells with 1 – 5 cm^2 active area) have been employed in investigations for temperatures up to 130°C (Badwal et al. 2013; Baglio et al. 2009; Xu et al. 2011).

High-Throughput Membrane Technology

Sanne Hermans¹ and Ivo Vankelecom²

¹Centre for Surface Chemistry and Catalysis, Department of M2S, Faculty Bioscience Engineering, KU Leuven, Leuven, Belgium

²Centre for Surface Chemistry and Catalysis, KU Leuven, Leuven, Heverlee, Belgium

The term “**high-throughput**” (HT) refers to the creation of a large output, i.e., a large amount of data that is obtained from simultaneous, parallel experiments. In general, HT methodologies are used to speed up the formulation and discovery

of new materials or the optimization of processes. They include a variety of advanced tools which allow fast parallel experiments, leading to higher productivities and shorter “time to market” times. While “HT” thus refers to the number of experiments, “combinatorial” strategies are related with the experimental design.

Besides automation (to whatever desired degree), a faster screening and more rapid optimization due to simultaneous testing, other **advantages** of HT technologies are the miniaturization (leading to smaller sample sizes and reductions in costs and waste streams) and the reproducible conditions between samples (as parallel tests are performed under identical experimental conditions, e.g., pressure, temperature).

Membrane technology can gain from the implementation of HT technologies on several levels. As membrane performance is influenced by a variety of parameters, an efficient HT screening of multiple variables can lead to the rapid development of new membranes and membrane applications.

HT devices can be implemented during the **membrane preparation**, the membrane screening, and the optimization of the membrane process parameters. The former relates to automated devices developed for weighing powders, dispensing liquids, homogenizing solutions, casting these polymer solutions, dip coating, etc. More details can be found on www.html-membrane.beand, www.porometer.com.

HT devices for **membrane screening** are commercially available for pressure-driven **liquid** separation systems with a variable number of membranes and different membrane areas per equipment (Vandezande et al. 2005; Cano-Odena et al. 2011; Van Doorslaer et al. 2010; www.porometer.com 2014). Commercially available HT devices also exist for **gas** separations, which were successfully applied to perform quality control tests at industrial-scale production and to quickly analyze membrane performance in diverse studies (Khan et al. 2010, 2013; Basu et al. 2011). The development of an HT membrane **bioreactor** (MBR) was also reported to simultaneously study the performance and fouling

properties of multiple membranes in one aerated MBR (Bilad et al. 2011). In addition, an HT cross flow filtration system was adapted into an online **fouling monitoring** system, allowing fouling studies of multiple membranes with high-quality imaging and a high reproducibility (Vanysacker et al. 2013). **Filter plate HT platforms** were also applied together with photoinduced graft polymerization or atmospheric pressure plasma-induced graft polymerization to synthesize and screen antifouling membranes (Zhou et al. 2009; Gu et al. 2013). An HT ionic conductivity apparatus and an HT mechanical testing apparatus for thin membranes were also reported (Zapata et al. 2009, 2010).

When new HT devices are developed, their **performance** should be evaluated based on their reproducibility (of the same sample), interchangeability (of sample positions), and scalability of the setup (compared to conventional methods) (Bilad et al. 2011).

Together with the application of HT technology, the **design of experiments** (DoE) has become increasingly important. As membranes can now be quickly synthesized and screened, the implementation of appropriate experimental design is crucial to obtain membranes with optimal performances. The aim is then to quickly eliminate experimental areas in which limited successes are expected so combined experimentation can be focused on potentially promising areas. An efficient search strategy combined with HT technology can rapidly lead to an optimum in a large parameter space, in contrast to the slower and less effective traditional parameter-by-parameter approach. Two important aspects are the certainty of finding an optimum and a rapid progression of convergence toward the optimal membrane performance.

Several experimental design types were already applied in membrane technology. Among them are artificial neural networks (ANNs) to predict membrane fouling and separation performances in both liquid and gaseous environments (Soleimani et al. 2013; Shokrian et al. 2010). Genetic algorithms (GAs) were applied to obtain an optimum in membrane

composition, separation modules and operating conditions, gas separation systems, and desalination units (Bulut et al. 2006; Vandezande et al. 2009; Yuen et al. 2000; Chang and Hou 2006; Guria et al. 2005). Genetic programming, Plackett-Burman design, Taguchi's method, response surface methodology, and fractional factorial design are other DoE types already employed in membrane technology.

The combination of HT technology with appropriate DoE clearly leads to the acceleration of acquiring output, hence, to a better understanding of the effects of parameters and the properties of new membrane materials and formulations. It can thus generate a significant decrease in cost and increase in efficiency during the discovery and optimization stages of membrane design and development processes.

Hollow Fiber

Khayet Mohamed

Department of Applied Physics, Universidad Complutense de Madrid, Madrid, Spain

In general a hollow fiber is a cylindrical geometry of any material having a hollow space with an external diameter approximately less than 0.5 mm (Fig. 1). It may have different cross-sectional shapes such as round, trilobal, pentagonal, octagonal, etc. Both smooth and corrugated-shaped hollow fibers were fabricated from different micro-engineered or smart spinnerets (Fig. 2). Various types of spinnerets (i.e., single or dual spinnerets, straight annular or conical spinnerets, microstructured orifice in

spinneret) with different configurations and dimensions are used in spinning hollow fibers (Khayet and Matsuura 2011). The difference between capillary, tubular, and hollow fiber is simply a matter of dimensions. The approximate diameter of a capillary membrane is between 0.5 and 5 mm, while that of a tubular membrane is higher than 5 mm (Mulder 1992). Since hollow fibers are mechanically self-supporting, the fiber dimensions are very important. A hollow fiber has an inner diameter (d_i) and outer diameter (d_o), while the thickness (δ) of the hollow fiber wall is the difference between the outer radius and the inner radius. The primary process variables establishing hollow fiber diameters and thickness are spinneret geometry. Other spinning parameters such as the bore liquid (fluid) flow rate, the dope extrusion rate, the take-up velocity and the air gap distance can modify the geometrical

Hollow Fiber,

and inner (b) microstructure (Reprinted from (Nijdam et al. 2005). Copyright 2005, with kind permission from Elsevier)

parameters of the spun hollow fibers. For example, Wu et al. (2007) found that the thickness of the poly(vinylidene fluoride), PVDF, hollow fibers prepared by wet spinning technique decreased with the increase of the internal coagulant (bore liquid) flow rate. For example, when the bore liquid flow rate was increased from 1.1 to 1.5 ml/min and further to 1.8 ml/min, the corresponding thickness of the PVDF hollow fibers decreased from 188 to 176 μm and further to 155 μm . An enhancement of the inner diameter and a reduction of the outer diameter of the hollow fibers with the increase of the bore liquid flow rate were detected.

The process of fabricating synthetic hollow fiber membranes is more difficult than that of flat sheet membranes. In general, the process is carried out by extruding or pumping a dope solution through a spinneret (Fig. 1) following different methods such as melt spinning, dry spinning, wet spinning, or dry/wet spinning. In melt spinning and dry spinning, the dimensions of the spinneret are not so crucial because the fiber dimensions are mainly determined by the ratio of the extrusion rate and “tearing rate” (Khayet and Matsuura 2011). In wet spinning and wet/dry spinning, the spinneret has a tube-in-orifice structure with typical dimensions 0.5–1 mm inner diameter and 0.9–2 mm outer diameter.

The first hollow fiber membranes were patented by Mahon in late the 1960s (Mahon 1966a, b). Various types of hollow fiber membranes, hydrophobic or hydrophilic, dense or porous, single or double layered, have been proposed for different membrane separation processes leading to a fast growth of synthetic membrane technology. Since then significant efforts have been made to develop new hollow fibers with desirable structures and morphologies. However, until now, various scientists admit that understanding the mechanisms of hollow fiber formation is rather qualitative than quantitative. It is not easy to control the characteristics of hollow fibers because various important spinning parameters are involved simultaneously. For example, the preparation of the hollow fiber membrane by the dry/wet spinning or wet spinning techniques requires both internal (bore liquid)

and external coagulants and involves more controlling parameters than the flat sheet membrane. Shape and dimension of the spinneret, viscosity of the spinning dope (whether hollow fibers can be spun from the dope), temperature of the spinning dope, properties of the internal and external coagulants, flow rate of the bore liquid, dope extrusion rate, length and humidity of the air gap, wind-up speed, and fiber take-up speed are some of those examples. As a consequence, the major parts of hollow fibers that appeared in the literature with different structures and morphologies are based mostly on trial-and-error experiments.

Hollow fibers are mechanically self-supporting, have good flexibility, and are easy to assemble in module and to handle for different applications. The feed is supplied to either the inside or outside of the fiber, and the permeate passes through the fiber wall to the other side of the fiber. The fiber wall may have an asymmetric structure being the active skin layer placed to the feed side. A bundle of hollow fibers are often mounted in a shell and tube module, which is featured by a very large packing density (i.e., high surface area per unit module volume), and therefore the size of the hollow fiber module is smaller than other modules for a given performance capacity. The packing capacity of a hollow fiber module may reach 500–9,000 m^2/m^3 resulting in a high productivity per unit volume.

Spinning corrugated hollow fibers is similar to spinning smooth cylindrical fibers; the only difference is the use of a modified spinneret (Cao et al. 2004; Çulfaz et al. 2010; Nijdam et al. 2005; Wang et al. 2004). For example, to prepare a hollow fiber with a corrugated inner microstructure instead of a cylindrical needle, the spinneret is fabricated with a structured needle. To spin a hollow fiber with a corrugated outer surface, a microstructured orifice is incorporated to the spinneret. Figure 2 shows SEM images of corrugated hollow fiber membranes.

The use of corrugated membrane surfaces is to enhance the heat and mass transfer by increasing the membrane surface area and the turbulence near the membrane surface. Corrugations act as turbulence promoters but also may lead to an increase of pressure drop in the flow channel. It

Hollow Fiber, Fig. 3 Cross-sectional structure of PVDF hollow fiber membranes prepared with wet spinning technique and dry/wet spinning technique using 20 wt.% PVDF in the solvent N-methylpyrrolidone (NMP) and

40 wt.% NMP aqueous solution as internal coagulant (Reprinted from (Bonyadi et al. 2007). Copyright 2007, with kind permission from Elsevier)

was observed that the size of the corrugations on the fiber was very sensitive to the air gap length and even disappeared from the external surface for high air gap lengths. When used in gas separation, the selectivity (oxygen/nitrogen) and permeance of polyethersulfone/polyimide (PES/PI) blend corrugated hollow fiber membrane were found to be similar to those of smooth cylindrical fibers (i.e., circular-shaped fibers) prepared under the same operating conditions. However, the gas permeate flow was increased by 19 %, which is the increase of membrane surface area due to corrugations (Nijdam et al. 2005). It is worth quoting that an increase of membrane surface area of 89 % can be obtained with a corrugated hollow fiber membrane (Çulfaz et al. 2010). Furthermore, PES/PVP blend hollow fiber membranes were used in *UF*, and it was found that the water permeability, molecular weight cutoff, and pore size distribution of both the corrugated and circular-shaped fibers were similar (Çulfaz et al. 2010). This indicates a higher permeate flow of the corrugated hollow fiber compared to the circular-shaped fiber and a similar *UF* separation factor.

Instabilities and irregularities may occur during hollow fiber spinning inducing corrugations at

their external or internal contours. These corrugations can be eliminated increasing the air gap distance (Fig. 3). The number of corrugations in the internal surface of the hollow fiber membranes is reduced approaching a final circular shape. The hydrodynamic instability, which leads to nonuniform cross-section and wavy geometry, might be due to the pressure induced in the nascent fiber (as a result of diffusion/convection, precipitation, densification, and shrinkage), which will buckle the rigid elastic shell formed at the interface between the bore fluid and the spinning dope solution (Bonyadi et al. 2007).

Hollow Fiber Carbon Molecular Sieve Membranes

Xuezhong He

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, Sør-Trøndelag, Norway

Carbon molecular sieve (CMS) membranes have been studied in more than twenty years as promising and energy-efficient membranes for gas separation. Due to their high permeability, selectivity, and also thermal and chemical stability under adverse and harsh conditions, the CMS membranes are becoming increasingly important for separating gas mixtures with quite similar molecular kinetic diameter. ^aDensity of carbons is 1.3–1.8 g cm^{-3} as compared to 2.2 g cm^{-3} for graphite (Koresh and Soffer 1983)

membranes can be prepared by controlling the carbonization procedure during carbonization of different polymeric materials such as polyimide, polyacrylonitrile (PAN), phenolic resin, poly(phthalazinone ether sulfone ketone), poly(phenylene oxide), cellophane paper, cellulose, and deacetylated cellulose acetate. The carbonization parameters (e.g., purge gas, purge gas flow rate, final temperature, heating rate, and final soak time) will affect the resulting carbon membrane performance, and the optimal condition was obtained on the basis of experimental design and statistical analysis to prepare the high-performance carbon membranes for a specific application as reported by He et al. (He and Hägg 2011a). Different techniques such as scanning electron microscopy (SEM), Fourier transform infrared spectroscopy (FTIR), and X-ray diffraction (XRD) have been used to characterize the membrane's structure and morphology. Figure 1 shows the cross section and inside surface of the precursors and HFCMs, respectively (He et al. 2011). The outer diameter and wall thickness of the HFCMs were approximately 250 μm and 30 μm , respectively, indicating a significant radical shrinkage comparing to the precursor membranes with 400 μm and 50 μm .

The pore size and pore-size distribution (PSD) can be estimated by gas gravimetric adsorption measurements equipped with a Rubotherm magnetic suspension balance (MSB) (Belmabkhout et al. 2009). The structural parameters of a cellulosic-based carbon membrane have been estimated from CO_2 sorption measurements, and a narrow pore-size distribution was found by He

et al. (He and Hägg 2012), and the results were shown in Table 1, which will be helpful to understand the transport mechanism through carbon membranes.

The operating parameters such as feed pressure, temperature, and flow rate of retentate will greatly affect the CMS membrane separation performances and need to be optimized for a specific application as reported by He et al. (He and Hägg 2011b). Considering the aging problem for most carbon membranes, different regeneration techniques can be used to recover the performances online or off-line (Lie 2005; Hagg and He 2011). In order to ensure the efficiency of the carbon membrane separation process, a hollow fiber membrane module should be designed and constructed. Figure 2 shows a schematic and lab-scale hollow fiber carbon membrane module (He and Hägg 2011b), while Fig. 3 shows a small pilot-scale module (designed by one of NanoGloWa project partner, HyGear B.V.) (He 2011). Single-gas permeability tests at different temperatures and pressures were mostly conducted by using the lab-scale module, while the small pilot-scale module was employed to test the gas mixture at a higher permeate flux in order to determine the gas composition more precisely.

Based on the experimental investigations and process simulations, the carbon membranes show high potential for selected industrial applications such as CO_2 - CH_4 separation for biogas upgrading (Hägg and Lie 2006), H_2 - CH_4 separation wherever relevant (Grainger and Hägg 2008), and CO_2 capture from flue gases (He and Hägg 2011b; He et al. 2009). Moreover, carbon molecular sieve

Hollow Fiber Carbon Molecular Sieve Membranes, Fig. 3 A small pilot-scale carbon membrane module (Designed by HyGear) (He 2011)

membranes also show a great potential in air separation, petrochemical, and high-temperature membrane reactor applications.

should be considered: flow in lumen, within membrane matrix, and in the extracapillary space (Nagy 2011, p. 179). Let us consider a steady-state, laminar, incompressible, isothermal, fully developed flow in vertically oriented tube; thus the Navier-Stokes equations (Bird et al. 1960) will be as the continuity equation:

$$\frac{1}{r} \frac{\partial}{\partial r}(rv_r) + \frac{\partial u}{\partial z} = 0 \quad (1)$$

where u is the axial convective velocity, m/s; v_r is the transverse convective velocity, m/s; and z is the axial space coordinate, m. The momentum equations are as

$$\begin{aligned} \rho \left(v \frac{\partial u}{\partial r} + u \frac{\partial u}{\partial z} \right) = & -\frac{\partial p}{\partial z} \\ & + \mu \left\{ \frac{\partial}{\partial r} \left[\frac{1}{r} \frac{\partial(ru)}{\partial r} \right] + \frac{\partial^2 u}{\partial z^2} \right\} \end{aligned} \quad (2)$$

$$\begin{aligned} \rho \left(v \frac{\partial v}{\partial r} + u \frac{\partial v}{\partial z} \right) = & -\frac{\partial p}{\partial r} \\ & + \mu \left\{ \frac{\partial}{\partial r} \left[\frac{1}{r} \frac{\partial(rv)}{\partial r} \right] + \frac{\partial^2 v}{\partial z^2} \right\} \end{aligned} \quad (3)$$

and for solute concentration in case of constant density

$$\begin{aligned} u \frac{\partial c}{\partial z} + v \frac{\partial c}{\partial r} = & \frac{\partial}{\partial r} \left(D \frac{\partial c}{\partial r} \right) + \frac{1}{r} \frac{\partial(Dc)}{\partial r} \\ & + \frac{\partial}{\partial z} \left(D \frac{\partial c}{\partial z} \right) \end{aligned} \quad (4)$$

where ρ is the density, p is the pressure, μ is dynamic viscosity, and g is gravitational acceleration.

Equations 2 and 3 may be reduced by considering the fact that for a small wall Reynolds number, the inertial terms can be negligible. In most viscous flows, normal stress effects, $\partial^2 u / \partial z^2$, are negligible when the ratio, r_o/L (L is length of capillary, r_o is lumen radius), is less than 10^{-2} , a condition that is satisfied in almost all hollow fiber membrane

Hollow Fiber Enzymatic Reactor, Modeling of

Endre Nagy
Research Institute of Chemical and Process
Engineering, University of Pannonia, Veszprém,
Hungary

Modeling of hollow fiber enzymatic reactor.

The complete description of the transport of fluid in hollow fiber capillary membrane requires that the local transport equations that describe the flow and transport conditions should be solved. The starting Navier-Stokes flow models (Bird et al. 1960) are very complex; significant simplification is needed to obtain applicable model for engineering points of view. In a capillary membrane with permeable wall, three regions of flow

devices. Depending on the transmembrane convective velocity, the axial velocity often can be much larger than that of the permeation rate. Due to its large values, the axial diffusion term can be neglected. The radial convective velocity is rather low; accordingly, momentum equation of the transverse velocity can be neglected. Accordingly, Eqs. 2 to 4 can be simplified as

$$0 = -\frac{\partial p}{\partial z} + \mu \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial u}{\partial r} \right) \quad (5)$$

The component balance will be as:

$$u \frac{\partial c_i}{\partial z} = D \frac{\partial}{\partial r} \left(r \frac{\partial c}{\partial r} \right) \quad (6)$$

When Eq. 6 is integrated twice with respect to r , one can get as

$$u = \frac{dp}{dz} \frac{r^2}{4} + A \ln r + B \quad (7)$$

For the hydrodynamic analysis in the lumen and in the shell, the continuity Eq. 1 and the momentum Eq. 5 have to be solved with suitable boundary conditions. In the lumen (t) these are

$$\text{at } r = 0 \text{ then } \frac{\partial u}{\partial z} = 0, \quad v = 0; \quad (8)$$

$$\text{at } r = r_0 \text{ then } v = 0 \quad (9)$$

Consequently it can be get

$$u = -\frac{r_o^3}{4\mu} \left(1 - \left[\frac{r}{r_o} \right]^2 \right) \frac{dp_t}{dz} \quad (10)$$

Replacing Eq. 10 into Eq. 5, one can get for the radial convective velocity in the lumen side (for distinction for the membrane's velocity, f subscript denotes the fluid phase here in the lumen side)

$$v_t = \frac{r_o^3}{\mu 8} \left\{ \frac{r}{r_o} - \frac{1}{2} \left(\frac{r}{r_o} \right)^3 \right\} \frac{d^2 p_t}{dz^2} \quad (11)$$

From Eq. 11 the wall velocity, v_w , can be given as

$$v_w = \frac{r_o^3}{16\mu} \frac{\partial^2 p_t}{\partial z^2} \quad (12)$$

The radial convective velocity through the membrane can also be expressed by the next equation

► **Biocatalytic membrane reactor: mass transport** as

$$v_M(r, z) = \frac{\kappa}{\varepsilon \mu} \frac{r_o}{r} \frac{p_t(z) - p_e(z)}{\ln(1 + \delta/r_o)} \quad (13)$$

From equality of Eqs. 12 and 13, a second-order differential equation can be obtained neglecting the radial pressure gradient (Nagy 2011, p. 187). Solving this equation the $p(z)$ and $v_w(z)$ functions can be obtained (Nagy 2011). This convection velocity can then be replaced in the mass balance equation for the membrane (see “► **Biocatalytic Membrane Reactor, Mass Transport** in).

Hollow Fiber Liquid Membrane

Vladimir S. Kislik

Campus Givat Ram, Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

Hollow fiber (HF) supported liquid membrane is a three-phase liquid membrane system in which the membrane phase (liquid) is held by capillary forces in the pores of microporous polymeric or inorganic hollow fibers. The design of the hollow fiber SLM module consists of a certain number of thin fibers, placed along the length of the shell. The feed phase is pumped through the fibers; the

Hollow Fiber Liquid Membrane, Fig. 1 Hollow fiber contained liquid membrane (HFCLM): (a) configuration of permeator shell and (b) side view of the permeator

Hollow Fiber Liquid Membrane,

Fig. 2 Scheme of the hollow fiber contactor with parallel flow of phases distributed U-shaped bundles of fibers with separated inlet and outlet end chambers. [*F* feed (donor) phase, *M* liquid membrane phase, *R* stripping solution, 1 hollow fiber for the feed, 2 glass tubulet, 3 glass tempering jacket of the contactor] (From Schlosser and Sabolova 2002)

pores in the fibers are filled with the LM solution, and the receiving (strip) phase is forced out through the sides of the shell. HF SLMs are schematically presented in the Figs. 1, 2, and 3. Compact and modular hollow fiber devices can be used with exceptionally high mass transfer area per unit equipment volume. Very often such HF systems are termed as contactor devices. Contactor devices are used as construction units in many of the SLM, HFCLM, and BLM systems. The theory

of the HFLM transport was developed by Sirkar et al. (see in Sirkar 1996) and Schlosser et al. (see in Schlosser and Sabolova 2002).

Different hollow fiber modules can be classified into several groups. One, termed as a “hollow fiber contained liquid membrane (HFCLM)” (Majumdar and Sirkar 1992) configuration, is shown in Fig. 1a. The process is achieved by packing thousands of microporous hollow fibers in a permeator shell filled with stationary liquid

Hollow Fiber Liquid Membrane,

Fig. 3 Scheme of the hollow fiber contactor of three phases with crossflow of LM phase: (1) body of element, (2, 3) hollow fiber in downstream and upstream part, (4, 5) inlet and outlet chamber, (6, 7) inlet and outlet tube, (8) flowing head, (9) central baffle; *F* feed, *E* LM phase, *R* strip solution (From Schlosser 2000)

H

membrane solution. The fibers are present in feed and strip sets very close to each other but with the ends of each set being separated. If the fibers are hydrophilic, the aqueous feed and strip flow through the lumen side of the fibers and fill the pores of the fiber; if fibers are hydrophobic, they are wetted by organic LM phase (Fig. 1b). So, reader can see that this is a hybrid system with combination of modified SLM and BLM configurations.

Hollow fibers in tube pertractor (Schlosser 2000) is another type of HF module (see Fig. 2) “with parallel flow consisting of one or two intermixed U-shaped bundles of microporous polypropylene fibers, inserted into polysulfon (or glass) tubes”. Pulsation of the LM phase along the fibers is used for better mixing.

One more type of the HF modules is presented schematically in Fig. 3. A crossflow with pulsation perpendicularly to fibers was used here. Some plate and frame HF modules were proposed. The

module with “fiber in fiber” units and crossflow of one phase is described in Ref. Schlosser and Sabolova (2002).

A capillary membrane module was developed (Teramoto et al. 2003) for gas separation. The concept of a capillary membrane apparatus is shown in Fig. 4. Both a feed gas and a LM solution are supplied to the lumen side (high-pressure feed side) of the capillary ultrafiltration membrane module and flow upward. The LM solution, which contains dissolved solute gas (CO_2), flows to the permeate side (low-pressure shell side), where the solution liberates dissolved gas to become a lean solution. The lean solution is returned to the lumen of the capillary module by a pump. In the shell side, dissolved gas is stripped from the liquid flowing down on the outer surface of the capillary and discharged from a vacuum pump through a liquid reservoir.

One more example of hollow fiber LM separation system is described as affinity dialysis (Devis

Hollow Fiber Liquid Membrane, Fig. 4 Schematic diagrams of facilitated transport of gas using capillary membrane module for removal and enrichment of carbon

dioxide: (a) experimental capillary membrane apparatus and (b) capillary membrane modules with permeation of carrier solution (From Teramoto et al. 2003)

et al. 1988) Water-soluble polymer (WSP) solutions as LM were immobilized into the pores of hollow fiber units (fibers of 5,000 molecular weight cutoff from Spectra/Por were used). Selective separation and concentration of both cations (Ca/Na, Cu/Zn) and anions (potassium chromate/sodium chloride) were tested. 2.5 % w/v aqueous solution of poly (2-acrylamido-2-methyl-1-propanesulfonic acid) (poly-AMPS) for cation separations and 5 % w/v solution of poly (ethylenimine) (PEI) for anion separations were used as LM. High concentration factor (50–75) and selectivity (30–40) were obtained.

Hollow fiber membrane catalytic reactors (HFMCr) and bioreactors (HFMBR) are relatively new developments of SLM techniques. The SLM reactors can be used to shift the equilibrium conversion (e.g., esterification reaction), to remove selectively products and by-products from the reaction mixture, and to supply selectively the reagents (e.g., oxygen for partial oxidation reactions) (Li et al. 2003). Application of SLM reactors appears of particular interest in hydrogen production and oxidation reactions. Applications of biocatalytic membrane reactors (Cussler and Ding 1995) provide an ideal support for catalyst immobilization due to their wide available surface area per unit volume and include

production of new or better foodstuffs, novel pharmaceutical products with well-defined enantiomeric compositions, conversion of lactose into glucose and galactose, the isomerization of glucose into fructose, and the separation of chiral isomers of acylated racemic amino acids and wastewater treatment.

The regeneration of degraded hollow fiber liquid membranes could be done by pumping the fresh LM at the lumen side of the support for a few minutes instead of the aqueous solution. Continuous impregnation of the membrane pores is possible as it is in the HFCLM devices or by adding membrane phase as an emulsion to the strip aqueous phases. It is termed the pseudoemulsion-based hollow fiber strip dispersion (PEHFSD) technique. The main drawback is pollution of the product with the membrane liquid.

Hollow Fiber Membrane Bioreactor for Cell Growth

Loredana De Bartolo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Hollow fiber membrane bioreactor consists of hollow fiber membranes parallel-assembled in an external shell, which is usually in the shape of a cylinder. The fibers are potted in the shell, thus creating a medium and a cell compartment which

are separated by the membranes. Hollow fiber membranes of suitable MWCO separate cells from the medium compartment allowing the communication between the compartments through the pores of fiber wall. Depending on the pore sizes, the passage of nutrients, metabolites, and catabolites occurs and cells are retained. The principle of a hollow fiber bioreactor based on hemodialyzer modules was first described by Knazek (Knazek et al. 1972). Usually cells are cultured in suspension or attached to the outer surface of the membranes in the extracapillary space. Culture medium containing nutrients flows in the lumen of the fibers and diffuses out through the pores of the fiber wall to the cells. The metabolic species together with waste molecules produced by cells permeates back into the fibers and is removed from cell compartment (Fig. 1).

As bioreactors, they are extensively used for production of biochemicals and for the development of bioartificial organs. Recently they found applications in tissue engineering applications for the development of tissue constructs, cell therapy, and the expansion and transdifferentiation of stem cells. Hollow fiber bioreactor offers several advantages for the culture and growth of adherent and suspension cells including: (i) an in vivo-like microenvironment regarding nutrient supply and metabolic waste removal as each fiber replicates a blood capillary, (ii) high surface area to volume ratio, (iii) cells can be grown to high density, (iv) cells are protected from shear stress, and (v) support of three-dimensional growth of cells for the development of tissue-engineered constructs. Different types of polymers (polyethersulfone, polysulfone, polyacrylonitrile, modified polyetheretherketone, polyamide, cellulose acetate, etc.), generally hydrophilic polymers or with moderate wettability, are used for the development of hollow fiber bioreactors in order to favor the adhesion of cells or the exchange of medium. Hydrophobic hollow fibers (e.g., polypropylene) are included in some devices for a separate oxygenation of cells (Flendrig et al. 1997). A major drawback of the hollow fiber bioreactors is represented by the mass transfer resistance due to the membrane because while it separates cells from the medium compartment,

Hollow Fiber Membrane Bioreactor for Cell Growth, Fig. 1 Schematic diagram of hollow fiber membrane bioreactor used for cell culture and growth: (a) cells are cultured in the extracapillary space, and the medium

flows in the lumen of fibers; (b) cells are cultured in the lumen of fiber, and the medium flows in the extracapillary space

it does reduce diffusion of nutrients and oxygen to the cells. In addition, fouling due to the adsorption of plasma proteins or the development of biofilms further increases the resistance to mass transport. In the membrane bioreactors, mass transfer is determined by the MWCO or pore diameter of membrane and occurs by diffusion and/or convection in response to existing transmembrane concentration or pressure gradients. Most of the bioreactors use membranes with MWCO ranging from 70 to 100 kDa that allow the transport of small molecules that are fed or produced by cells but exclude proteins with high MW such as immunoglobulins and cells. These membranes provide immunoprotection, which is important when the devices are used in the organ replacement therapy in order to avoid the passage of immunocompetent species present in the patient's blood. Other bioreactors use microporous membranes with a large pore diameter ($0.2\ \mu\text{m}$) that permit the free passage of proteins, toxins, and clotting factors, but they exclude the passage of cells. The advantage of using a membrane with large pore diameter is that it increases the fluid convection improving the mass transfer conditions. Several hollow fiber membrane bioreactors

have been developed for the culture of cells that grow in adhesion and/or in suspension. Different configurations have been investigated for the culture and growth of primary cells (e.g., lymphocytes, hepatocytes, pancreatic islets, neurons, osteoblasts, fibroblasts), cell lines, progenitor cells, and stem cells (De Bartolo and Bader 2013). Usually cells are cultured in adhesion or suspension outside the fibers, and the medium flows in the lumen of fibers (De Bartolo et al. 2007a). In other bioreactors cells are cultured inside the lumen of fibers, and the medium flows in the shell of fiber (Fig. 1) (Nyberg et al. 1994). More complex devices have been explored for the culture of hepatocytes, stem cells, and progenitor cells that include the use of different fibers. A bioreactor with four interwoven independent capillary membrane systems that serve different functions has been developed by Gerlach et al. (1994). The cells are cultured on the outer surface and among the capillaries. Each fiber type exhibits a different function: silastic membranes for oxygen supply and removal of carbon dioxide, polyamide fiber for the plasma inflow, polyethersulfone fiber for the plasma outflow, and hydrophilic polypropylene

membranes for the sinusoidal endothelial coculture. A crossed hollow fiber membrane bioreactor was developed as an *in vitro* liver tissue model to study disease, drugs, and therapeutic molecules alternative to animal experimentation (De Bartolo et al. 2009). The bioreactor consists of two types of fibers with different MWCO and physicochemical properties cross-assembled in alternating manner: modified polyether-etherketone and polyethersulfone used for the medium inflow and outflow, respectively. The combination of these two fiber sets produces an extracapillary network for the adhesion of cells and a high mass exchange through the crossflow of culture medium. This bioreactor has been developed for the culture of human hepatocytes and expansion and differentiation of liver progenitor cells. Multibore fiber membrane bioreactor consisting of modified polyethersulfone fiber has been developed for the long-term maintenance of human hepatocytes. Each fiber is composed of seven compartments that communicate through a porous foamy support structure that is located in between the capillaries. Cells have been cultured inside the lumen of the multibore fibers and lumen in the shell compartment (De Bartolo et al. 2007b).

Hollow fiber membrane bioreactors have a great potential for the expansion and differentiation of embryonic and adult stem cells, which have ability to either self-renew or differentiate into multiple cell lineages. These properties make stem cells attractive as a cell source for cell therapies, tissue engineering, and model systems for drug screening. Depending on the application, hollow fiber membrane bioreactors can be used for the production of expanded stem cells with uniform properties and/or for a controlled and reproducible differentiation into selected mature cell types (Salerno et al. 2013). They are particularly advantageous with respect to the other culture systems because of their capacity to ensure a more homogeneous environment, to monitor key culture parameters (pH, temperature, oxygen, etc.), and to guide the transdifferentiation of cells by engineering membranes with targeted properties.

Hollow Fiber Membrane Module

Joerg Balster

Application Technology, Evonik Fibres GmbH, Schoerfling, Austria

Synonyms

[Hollow fiber membrane](#); [Hollow fiber module](#)

The hollow fiber membrane module as well as a capillary membrane module assembles as shell-and-tube heat exchanger. It consists of a large number of hollow fibers assembled in a module,

Hollow Fiber Membrane Module, Fig. 1

Schematic of a hollow fiber module with the feed on the inside of the fiber (bore side feed) and the feed on the outside of the fibers (shell side feed) (Taken from Scholz et al., 2011)

as shown schematically in Fig. 1 (Scholz et al. 2011; Mulder 1997).

The free ends of the fibers are potted with agents such as epoxy resins, polyurethanes, silicone rubber, thermoplastics, thermosets, or inorganic cements. In some cases, they can also be fused by heating. The difference between hollow fiber modules and capillary modules is a matter of dimensions while the module concepts are the same (Scholz et al. 2011; Mulder 1997).

Hollow fibers consist of a porous, nonselective support layer (about 200 μm) and an active layer (<40 nm). The active layer is the actual membrane, but due to its small thickness, it must be supported by a thicker layer in order to obtain mechanical strength, to withstand the pressure difference between feed to permeate side (Scholz et al. 2011).

The hollow fiber membranes are self-supporting. Two types of module arrangement can be distinguished: (i) where the feed passes through the bore of the hollow fiber (lumen) whereas the permeate is collected on the outside of the hollow fibers (Fig. 1 “Inside Feed”) and (ii) where the feed enters the module on the shell side of the hollow fibers (external) and the permeate passes into the fiber bore (Fig. 1 “Outside Feed”). The choice between the two concepts is mainly

Hollow Fiber Membrane Module, Table 1 Properties of hollow fiber modules (Taken from Scholz et al. 2011)

	Hollow fiber module
Structure	Self-supporting
Active layer	Inner/outer diameter
Feed	Lumen/shell side
Inner diameter	40–250 μm
Outer diameter	80–400 μm
Packing density	<10,000 m^2/m^3
Allowed pressure	100 bar shell side; 15 bar lumen side
Applications	GP, RO, DL

based on the application where parameters such as pressure, pressure drop, type of membrane available, etc. are important. Depending on the concept chosen, asymmetric hollow fibers are used with their skin on the inside or on the outside (Mulder 1997).

The hollow fiber module is the configuration with the highest packing density, which can attain values of 30,000 m^2/m^3 (Scholz et al. 2011). The typical properties and dimensions of hollow fiber membrane modules are summarized in Table 1 (Melin and Rautenbach 2007):

The advantages of hollow fiber modules are the following (Melin and Rautenbach 2007):

- Highest packing density and membrane area to module volume ratio
- Cheapest manufacturing costs

The disadvantages are the following:

- Mostly laminar flows (increased mass transfer limitations)
- Lower pressure resistance

Up to 80 % of the commercial gas separation membranes are being formed into hollow fiber modules (Baker 2002).

Hollow Fiber Modules for Desalination

Chunrui Wu

State Key Laboratory of Hollow Fiber Membrane Materials and Membrane Processes, Institute of Biological and Chemical Engineering, Tianjin Polytechnic University, Tianjin, China

The desalination of brine is commercially implemented by reverse osmosis (RO),

multi-effect evaporation (MED), and multistage flash (MSF) distillation. Although such conventional processes are widely used, there is a need for novel desalination techniques such as membrane distillation (MD) which may be much cheaper and have other distinct advantages. The membranes used in MD processes can be divided into two forms: flat sheet membrane and hollow fiber-based membrane. Most of the work on hydrodynamic improvement in MD studies has focused on flat sheet membrane modules. They have small membrane areas and thus are limited to laboratory research. In industry, hollow fiber-based membrane modules are preferable due to their larger membrane area per unit volume and reduced vulnerability to temperature polarization. Based on the MD mechanism, the obtained flux depends both on the membrane permeation properties and the flow geometry in the membrane modules. Therefore, the research on the flux enhancement in MD can be divided into two large areas, the fabrication of highly permeable membranes and designs of optimized membrane modules.

Recently, many designs of hollow fiber membrane modules have been proposed in order to suppress the undesirable temperature and concentration polarization phenomena. The performances of different polyvinylidene fluoride (PVDF) hollow fiber membranes have been studied in different size modules (Fig. 1). The properties of the laboratory modules made, which depend on the experiment's requirements, can be changed. The modules of PVDF have a stable performance and can be used in reverse osmosis drained wastewater treatment (Wu Chunrui et al. 2010). The study in comparison of three membrane distillation configurations and seawater desalination by vacuum membrane distillation (VMD) showed that the shell-and-tube capillary membrane module had unique advantages such as flexible and changeable (Chen Huayan et al. 2011).

Li et al. designed a novel membrane device made of novel membranes. To enhance the brine side heat transfer coefficient substantially, they employed cross flow of hot brine over the outside surface of hollow fiber membranes. To achieve a compact device, they designed a hollow fiber

Hollow Fiber Modules for Desalination,

Fig. 1 Modules of PVDF hollow fiber membrane

Hollow Fiber Modules for Desalination,

Fig. 2 Rectangular cross flow test module without face plates

Hollow fibers

device built in a rectangular cross flow mode for the hot brine to flow over the outside of the fibers (Fig. 2) (Li and Sirkar 2005). Simplified models have been developed to describe the observed performance of the modules in different MD

processes (Gilron et al. 2007). The MD experiment's results have shown that the modules' performance was quite satisfactory and the design of module enhanced the heat transfer as well as mass transfer.

Hollow Fiber Modules for Desalination, Fig. 3 Different modules design and hollow fiber geometries configurations

H

Different hollow fiber configurations with wavy geometries (twisted and braided) for flux enhancement in MD process have been developed by Teoh et al. in 2008 (Teoh et al. 2008). The different module designs, such as baffles and spacers, were incorporated during the module fabrication process, as illustrated in Fig. 3. A single sieve spacer was placed about 7.5 cm away from both ends of the module in the spacer module designs. And the distance between each spacer for the two or three-sieve spacers configurations was 5 or 3.75 cm. Similarly, the helical baffle introduced in the central of the module which was surrounded by hollow fibers was placed 5 cm away from the both ends of the membrane module. The results showed that the application of baffles can increase the feed side heat transfer coefficient. In addition, using spacers among the fibers may increase the effective membrane area 18–33 %. Lastly, the application of different hollow fiber configurations with wavy geometries could lead to flux enhancements as high as 36 % without inserting any external turbulent promoter. In overall, the goal of greater flux enhancements with modified hollow fiber membranes modules was achieved.

Five types of novel hollow fiber module configurations have been designed and constructed by Yang et al. for the direct contact membrane distillation (DCMD) process in 2011

(Yanga et al. 2011). The novel designs could be divided into structured-straight fibers, curly fibers, central tubing for feeding, spacer-wrapped fibers, and spacer-knitted fibers. The test results showed that the vapor permeate flux could be enhanced from 53 % to 92 % compared with the conventional module, and the spacer-knitted module had the best performance. Experiments reveal that improved fiber geometries or arrangements can provide a better flow distribution, thus much lower pumping energy cost and higher thermal efficiency could be accomplished (Fig. 4).

In 2005, Liu et al. prepared some coiled hollow fiber membrane modules and experimentally examined their mass transfer performances (Liu et al. 2005). The research results showed that, compared with the conventional straight module, the mass transfer in both tube and shell side of the coiled hollow fiber module could be remarkably enhanced. And the mass transfer coefficient of the coiled module at either side of membrane was more than two times higher than that of the straight module. The configurations of the coiled hollow fiber membrane module and the conventional straight module are shown in Fig. 5. Different geometric coiled modules were employed to study the influences of the factors such as coiled diameter, wind angle, and internal diameter of fibers on mass transfer. It was found that wind angle had an

important influence on the fluid condition of the coiled module and its mass transfer.

Geng et al. developed a new air-gap membrane distillation (AGMD) module with internal latent heat recovery configuration (Geng et al. 2014). The novel module is consisted of parallel hollow

fiber membranes and heat exchanged hollow fibers (Fig. 6). They investigated the influences of operating factors such as feed flow rate, feed temperature, and feed initial concentration on AGMD process. Simultaneously they established a theoretical model based on the energy and mass

Hollow Fiber Modules for Desalination,

Hollow Fiber Modules for Desalination, Fig. 6 Schematic presentation of the novel AGMD module

balances of the hot feed side in membrane. The model was used to calculate the temperature and the vapor permeate flux distributions along the hollow fiber membrane. The performance of the AGMD module was experimentally demonstrated under different operating conditions, and the results showed that the energy of AGMD process was recycled effectively, simultaneously, a high gained output ratio (GOR) of 5.7 was obtained.

Hollow Fiber Spinning

Khayet Mohamed

Department of Applied Physics, Universidad Complutense de Madrid, Madrid, Spain

Hollow fibers are fabricated by extruding or pumping a dope solution through a spinneret following different methods such as melt spinning, dry spinning, wet spinning, or dry/wet spinning. The spinneret has a tube-in-orifice structure with typical dimensions 0.5–1 mm inner diameter and 0.9–2 mm outer diameter. A simple experimental device for the hollow fiber spinning by dry/wet spinning is shown in Fig. 1. In some spinning systems, a circulation pump is employed instead of the gas cylinder (i.e., nitrogen) to drive the dope solution through the spinneret. The dope solution under gas pressure is forced to pass through the spinneret the annular space of the spinneret. The internal coagulant (bore liquid) is driven through the central tube either by the gravity force or by means of a circulation pump. The dope solution, after being extruded from the spinneret, enters into a coagulation bath before traveling a certain distance of air gap (i.e., the distance between the spinneret and the coagulation bath), which may

vary from 0 (wet spinning) to more than 1 m. In wet spinning, the dope solution is extruded directly into the precipitating liquid (external coagulant). In this technique the spinneret is submerged in the coagulation bath causing immediate fiber precipitation and solidification. In the dry/wet spinning, coagulation of the internal surface of the nascent fiber starts immediately after its extrusion from the spinneret, whereas the external surface experiences coalescence and orientation of polymer aggregates through the air gap before gelation in the external coagulation bath takes place. After spinning, the nascent fibers are oriented by means of guiding wheels and finally pulled into a collecting reservoir by a wind-up drum. Only a fiber with sufficient mechanical integrity can pass over the guiding wheels to the collecting bath. During spinning, the take-up velocity is generally kept at the same speed as the free-falling velocity of the nascent fiber to prevent stretching of the fiber (Khayet and Matsuura 2011).

Prior to the drying step, the spun hollow fibers usually go through the solvent exchange and other posttreatment procedures in order to remove residual solvents, prevent hollow fiber shrinkage, eliminate possible defects, and reduce pore collapse. Conventional solvent exchange step before drying consists of immersion of the obtained hollow fibers in one non-solvent or successive immersion in several non-solvent mixtures containing components with lower surface tensions than water. Mixtures of water with increased concentrations of lower surface tension components such as methanol and ethanol can be employed. Hexane can also be employed for further solvent exchange since its surface tension is even lower than alcohols and it is volatile.

The hollow fibers can be spun at room temperature (20–22 °C) or at a temperature higher than the ambient temperature. During spinning the take-up speed is normally maintained nearly the same as the dope extrusion speed so that no external elongational stresses, except gravity, can be applied to the nascent hollow fiber. A very large air gap distance may lead to flow instability of the fiber resulting in nonuniform fiber dimensions. Examples of typical applied spinning parameters

Hollow Fiber Spinning,

Fig. 1 Schematic diagram of a typical hollow fiber spinning system: 1 spinning dope tank; 2 regulating pressure valve; 3 pressure gauge; 4 dope vessel; 5 dope valve; 6 bore liquid vessel; 7 bore liquid pump; 8 spinneret; 9 air gap; 10 coagulation bath; 11 wind-up drum; 12 fiber collecting reservoir; 13 wash water (Reprinted from Khayet et al. (2009). Copyright 2009, with kind permission from Elsevier)

of different poly(vinylidene fluoride), PVDF, dope solutions are bore liquid flow rate (0.5–3 ml/min), air gap distance (0–3 cm), take-up speed (free fall, 5 m/min), dope solution flow rate (2–4 ml/min), applied pressure over the dope solution (138–207 kPa), and temperature of the coagulants (15.5–25 °C) (Wu et al. 2005, 2006, 2007; Wang et al. 2008).

In dry spinning, air or an inert gas is used instead of the bore liquid so that solidification is achieved through evaporation of the solvent. As the dope solution exit the spinneret, air or an inert gas is used to evaporate the solvent(s) so that the fiber solidifies and collected on a take-up wheel. Spinning is followed by stretching of the as-spun fibers to orient the polymer chains along the gas gap (i.e., fiber axis). The as-spun fibers do not come into contact with a precipitating liquid. In dry spinning and melt spinning, the dimensions of the spinneret are not so crucial because the fiber dimensions are mainly determined by the ratio of the extrusion rate and “tearing rate” (Mulder 1992). The gas flow

used for solvent evaporation and solidification of the fibers influences to a significant extent the quality of the produced fibers.

In melt spinning, the polymer is first compressed, heated, and melted by an extrusion screw, then forced through the annular space of the spinneret. The polymer solidifies by cooling after being extruded from the spinneret and then collected by means of take-up wheels. The spinning rate in melt spinning (thousands of meter per minute) is much higher than that used in the dry/wet spinning technique (meters per minute) (Mulder 1992).

The spinneret geometry, the dope solution, and the spinning conditions (bore fluid type and its flow rate, dope solution extrusion rate, take-up speed, air gap distance, external coagulant, spin draw ratio, spinning temperature, cold stretching, etc.) affect the hollow fiber geometrical parameters (inner and outer diameters, thickness), its internal structure, as well as the structural morphology of the inner and outer surfaces.

Homogeneous Anion-Exchange Membranes

Mitsuru Higa

Graduate School of Science and Engineering,
Yamaguchi University, Ube, Yamaguchi, Japan

Anion-exchange membranes (AEMs) are classified into two types by their microstructure: heterogeneous and homogeneous. Homogeneous AEMs consist of a uniform membrane matrix with anion-exchange groups (positively charged groups) and, in many cases, reinforcing materials such as woven cloth or net. Various methods have been reported for preparing homogeneous AEMs; however, almost commercial homogeneous AEMs are copolymer membranes composed of styrene and divinylbenzene (DVB) with benzyl trimethylammonium groups. Figure 1 shows a schematic diagram of a typical preparation method (paste method) of the AEMs

Homogeneous Anion-Exchange Membranes, Fig. 1 A typical preparation method of AEMs (paste method). 1 Reserve roll of reinforcing fabric, 2 reserve roll of separating film, 3 receiving roll, 4 paste (mixture of vinyl monomers, inert polymers, initiator, additives, etc.) reservoir, 5 expand roll, 6 press roll, 7 guide roll

(Sata 2004). A monomer mixture consisting of chloromethylstyrene (CMS)/DVB, acrylonitrile-butadiene rubber, and benzoyl peroxide to initiate polymerization was used to prepare the paste. A reinforcing material such as woven poly (vinyl chloride) cloth, reserved to roll 1, was dipped in the paste reservoir 4. A separating film such as poly(ethylene terephthalate) was fed from roll 2. The reinforcing material coated with the paste was wound on roll 3 in layers with the separating film. In this way, the paste (the monomer mixture) was continuously coated on the reinforcing material and covered on both sides with the separating film. A precursor membrane was obtained by heating the resultant composite at 80 °C for 10 h under a nitrogen atmosphere to polymerize the monomers. An ion-exchange group was introduced by quaternization by immersing the precursor membrane in an aqueous solution of 1.0 mol/dm³ trimethylamine at 30 °C for 20 h. The cross-linker content (CLC) in the mixture was changed to control the network structure of the membranes. The CLC was defined as follows:

$$CLC = \left(\frac{C_{DVB}}{C_{CMS} + C_{DVB}} \right) \quad (1)$$

where C_{DVB} and C_{CMS} are the content of DVB and CMS in the mixture. The value of CLC is controlled to optimize the fundamental

physicochemical properties, transport number of anions and electrical resistance, to their applications. In general, the transport number and electrical resistance of AEMs increase with increasing *CLC*.

Other preparation methods of homogeneous AEMs have been reported such as: (a) modification of aromatic polymer. An aromatic polymer such as poly(ether-ether-ketone) is chloromethylated using chloromethyl ether in the presence of a catalyst, and then the chloromethylated polymer is quaternized using triethylamine. The quaternized polymer solution is cast to form an AEM. (b) Pore-filling method. AEMs are prepared by filling the pores of a porous film (e.g., porous polyethylene) with a mixture of vinylbenzene-based monomers, a cross-linking agent, and an initiator. Then, thermal cross-linking polymerization is performed. Finally, quaternary ammonium groups are introduced. (c) Electron-beam-induced graft polymerization. A polymer film such as high-density polyethylene is grafted by electron-beam-induced graft polymerization with CMS and DVB. The quaternary ammonium groups are introduced by treating the grafted film with trimethylamine.

Honeycomb Ceramic Membranes

Wanqin Jin

State Key Laboratory of Materials-Oriented Chemical Engineering, Nanjing University of Technology, Nanjing, China

Honeycomb structure body possesses a specified pore distribution on the surface of the partition walls and an enlarged porosity in addition to thin partition walls of a prescribed value. Because of the special structure, ceramic honeycombs are

widely used as catalyst supports and as particulate filter (Pronob 1997).

The honeycomb membrane is viewed as a type of multichannel membranes. It brings the element of ceramic honeycomb monoliths, with proprietary modifications, as membrane supports. Such large honeycomb structures are characterized by very high membrane area, up to several hundred-fold the amount of area in most commercially available ceramic membrane elements. Variations such as adding the pore numbers and decreasing the diameter of every pore will improve membrane area. The loading density of ceramic membrane is also improved with the honeycomb design. The cross section schematic diagram of honeycomb ceramic membrane is shown in Fig. 1.

However, there are disadvantages in honeycomb ceramic membrane. The first disadvantage is asymmetry distribution of fluid. Because of the honeycomb element of high sectional area, the volume of membrane is relatively large. It will lead to the consequence that the velocity of fluid in honeycomb ceramic membrane which is coaxial to pipe of raw materials is higher than fluids from other fluids. So it is hard to control concentration polarization in membrane as the asymmetry distribution of fluid. Another disadvantage is high permeate pressure. With decrease of pore diameter and pore wall thickness, more permeate liquid passes through inner pore of honeycomb ceramic support. So the transmission resistance is improved, permeation flux is decreased. Using the method to change parts of membrane pores to permeation flux channel, or to slot ports, permeation length is decreased and permeation flux is improved. But unit area of membrane decreases in some extent. So post-processing of honeycomb ceramic membrane is extremely important, despite of its difficulties. The other disadvantage is high cost with low yield. Since the preparation process is very complex, probabilities of membrane defects are much higher. Those defects can be improved with designed membrane modules.

The use of honeycomb structure in ceramic membrane is promising. It has been used in reverse osmosis desalination for sea water. Exploratory and advanced developments have been accomplished in some companies. With

Honeycomb Ceramic Membranes, Fig. 1 The cross section schematic diagram of honeycomb ceramic membrane

mean pore size of 50 nm, honeycomb ceramic membrane improves the quality of pure water in osmosis process to 86 %. And the permeation flux can be kept in about 150 L/(m²·h·bar) according to experiments mentioned in several articles.

Honeycomb Membrane Structure

Annarosa Gugliuzza
 Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

Air bubble geometry; Breath figure membranes; High-defined porous films

Honeycomb membrane structures are a competitive and concrete example of highly ordered polymeric patterns, which can work as perm-selective interfaces in advanced membrane processes (Gugliuzza et al. 2008). They are prepared by using a bioinspired nanotechnology, which exploits the ability of water to condense from fog to cooled surfaces and self-assemble in semi-crystalline lattices under dragging Marangoni convection and capillary forces (Gugliuzza et al. 2009). When the solvent evaporates, a difference of temperature is established between the cooled liquid film and nearby humid atmosphere, causing droplets to condense and rearrange in honeycomb-packed geometries. The droplet lattice works as a real pore builder through the polymeric solution, leading to the formation of air bubble arrays. Each single cavity can be regarded as the result of the imprinting action of the droplets. No coalescence is observed when a stable polymeric protective layer is formed around each single droplet during sinking (Fig. 1).

Under suitable experimental conditions, droplet dynamics can be directed towards the formation of membranes with modulated spherical pore size, monodisperse pore distribution, long-range order, and high interconnectivity (Speranza et al. 2010). The typical hexagonally packed geometry, resembling natural structures, produces very high interfacial area necessary to promote large mass transfer through the membranes. Also, the complete propagation of the porous structure along the entire membrane thickness reduces significantly any resistance to transport,

Honeycomb Membrane Structure, Fig. 1 Representative mechanism for the formation of honeycomb membranes

yielding performance higher than that observed for commercial tubular modules when worked in membrane distillation plants (Gugliuzza et al. 2008).

The singular topography of honeycomb membranes has significant consequences on wettability as well. The hexagonally packed geometry increases the surface roughness according to zig-zag geometrical model (Thomas 1999), preventing wetted pores owing to air pockets uniformly distributed through the surface. Indeed, the air is easily entrapped inside the big cavities according to the Cassie–Baxter model, thereby minimizing the spreading of the liquid and improving significantly the water resistance of the membrane.

Chemical and structural features make the honeycomb membranes ideal interfaces for some membrane contactors operations, including membrane distillation, membrane crystallization, and membrane emulsification (in particular premix membrane emulsification), where large mass transfer along with the establishment of durable interfaces at the entrance of each single pore are in great demand. Moreover, the extraordinary regularity and stability of 3D polymeric architecture make these membranes suitable for working as molecular reservoirs, scaffolds for tissue engineering, and platforms for sensors.

Compared with traditional manufacturing procedures, the one-pot fabrication of micro- and nanostructured membranes, based on the self-

assembly of sacrificial natural building blocks, is regarded as a novel, flexible, and eco-friendly technology. This approach is expected to open new routes to fabricate a large variety of ordered functional membranes for industrial applications, but also for handling the miniaturization of light-weight systems perceptively.

Hybrid Membranes

Mario Aparicio
Instituto de Ceramica y Vidrio (CSIC), Madrid,
Spain

The term “hybrid membrane” more commonly refers to a membrane formed by at least two components of different chemical nature (considering chemical-bond modes) from the groups of metals, organic materials and their polymers, and inorganic materials.

Hybrid membranes can be classified into two main types, depending on the nature of the interaction between components: (1) systems where there are no covalent or ionic-covalent bonds between components, only Van der Waals, hydrogen bonding, or electrostatic forces, and (2) systems where at least parts of the components are linked through strong covalent or ionic-covalent bonds (Sanchez and Gómez-Romero 2004). The first type can also be named as composites, or nanocomposites, where at least one of the components' domains has a dimension ranging from a few angstroms to several nanometers.

The main objective in the synthesis of hybrid membranes is the performance improvement of the material for different applications. It is obvious that the properties of these membranes are not only the sum of the individual contributions of both components, and interfaces can play a significant role.

The high number of parameters involves in the design and preparation of hybrid membranes: the number of components, composition, components ratio, size, shape, and kind of interaction between components results in an almost infinite number of combinations.

Hybrid Modeling of Membrane Biofilm Reactors

Endre Nagy
Research Institute of Chemical and Process
Engineering, University of Pannonia, Veszprém,
Hungary

The immobilized whole cells in a membrane bio-reactor are grown within the fibers and/or in the

extracapillary space-forming biofilm. The conventional biofilm is increasingly used for wastewater purification, oxidation of organic components, nitrification, etc. as they are environmentally friendly and less energy intensive. Biofilm formation is a complicated dynamical process governed by various physical and chemical principles and biological protocols. Biofilms are agglomerations of microorganisms or bacteria whose structure can be homogeneous, in case of sufficient substrate level, or heterogeneous when the diffusion is rate limiting, due to the change of the nutrient concentration in axial direction (Gavin and Gillian 2012). This circumstance can alter the value of transport parameters (diffusion coefficient, convective velocity) and can even alter the biochemical reaction rate (the consumption rate of nutrient). The variation of cell density is also true in the biocatalyst membrane layer perpendicular to the inlet surface. Increasing distance from the surface can mean decreasing nutrient concentration. That is why the variability of the transport parameters should also be taken into account. Assuming simultaneous effect of two substrates, namely, oxygen and carbon sources, the mass balance for diffusive flow can be given for a sheet membrane layer with constant parameters, as

$$D \frac{d^2 c_{O_2}}{dy^2} - \frac{1}{Y_{XO_2}} \frac{\mu_{\max O_2} c_{O_2}}{K_{MO_2} + c_{O_2}} \frac{c_A}{K_{MA} + c_A} = 0. \quad (1)$$

The quasi-analytical approach of solution of Eq. 1 is given, e.g., by Nagy (2011). Let us give here the rate equations for limiting cases with constant c_A concentration in the biofilm. Two important cases can be distinguished, namely, when the outlet (at $y = \delta$) diffusive flow is zero ($dc/dy = 0$, the support membrane layer is impermeable) and $dc/dy \neq 0$ at $y = \delta$ (there is sweep phase on the permeate side of a permeable membrane). The mass transfer rates are given for these cases, for first-order reaction by Eqs. 2 and 4 and for zero-order reaction by Eqs. 5 and 7, respectively. The transfer rate in the presence of convective flows is given in entry biocatalytic membrane

reactor: mass transport ($c = c_{O_2}$, Y_{XO} is yield coefficient):

$$J = \sqrt{k_1 D} \tanh \vartheta c^o \quad (2)$$

with

$$\vartheta = \sqrt{\frac{k_1 \delta^2}{D}}; \quad k_1 = \frac{1}{Y_{XO}} \frac{v_{\max}}{k_{MO_2}}$$

$$J = \frac{\sqrt{k_1 D}}{\tanh \vartheta} \left(c^o - \frac{c_\delta}{\cosh \vartheta} \right) \quad (3)$$

$$J = \frac{D}{\delta} \vartheta^2 c^o \quad (4)$$

with

$$\vartheta = \sqrt{\frac{v_{\max} \delta^2}{D Y_{XO_2}}}$$

$$J = \frac{D}{\delta} \left(c^o - c_\delta - \frac{\vartheta^2}{2} \right) \quad (5)$$

In order to overcome the diffusive mass transport limitation of nutrients, especially of the sparingly soluble oxygen, the substrate might be fed on both sides of the biofilm applying oxygen permeable support layer. The sum of the mass transfer rates for first- and zero-order reactions can be expressed by Eqs. 6 and 7, respectively. The substrate concentrations of the two sides of the biofilm layer are c_1^o and c_2^o . The substrate concentration curve has inflection point at $Y = Y_1$ ($Y = y/\delta$):

$$J = \frac{\sqrt{k_1 D}}{\tanh \vartheta} \left\{ \left(1 - \frac{1}{\cosh^2(\vartheta Y_1)} \right) c_1^o + \left(1 - \frac{1}{\cosh^2(\vartheta [1 - Y_1])} \right) c_2^o \right\} \quad (6)$$

with

$$\frac{c_1^o}{c_2^o} = \frac{\cosh(\vartheta Y_1)}{\cosh(\vartheta [1 - Y_1])}$$

$$J = \frac{D}{\delta} \left\{ c_1^o + c_2^o - 2c_1^o \left(1 - \frac{\vartheta^2}{2} [2Y_1 - 1] \right) + \vartheta^2 \right\} \quad (7)$$

with

$$\begin{aligned} c_1^o \left(1 - \frac{\vartheta^2}{2} [2Y_1 - 1] \right) \\ = c_2^o \left(1 + \frac{\vartheta^2}{2} [2Y_1 - 1] \right). \end{aligned} \quad (8)$$

The Y_1 inflection point can be determined by Eq. 8 and then the mass transfer rate by Eq. 7 as well. Detailed solution of Eq. 1 is published by Nagy (2011), recommended explicit expression for the mass transfer rate. The biofilm can involve several substrates with several parallel and/or consecutive reactions as this is the case of aerobic wastewater treatment. System of the differential mass balance equations of the reactants should be solved in order to get their concentration distributions and the mass transfer rates of the transferring substrates.

Hybrid Organic-Inorganic Nanostructured Membranes

Mario Aparicio
Instituto de Ceramica y Vidrio (CSIC), Madrid,
Spain

A hybrid organic-inorganic nanostructured membrane is a specific kind of hybrid membrane formed by at least two components from organic materials and their polymers and inorganic materials. The components of this kind of hybrid membranes have dimensions up to several nanometers, and components are linked through covalent or ionic-covalent bonds.

Improved and also new properties are expected in this specific kind of hybrid membranes because of the combination of two very different materials and their chemical interactions. For example, it is possible to obtain membranes with a high flexibility and processability, such as a polymer, but with the improved thermal and chemical stability, and mechanical strength of inorganic materials (Sanchez et al. 2005).

The possible applications of these hybrid membranes are increasing continuously. For example, an antimicrobial drug (substituted 1,3,4-oxadiazole) with functionalized silica was successfully incorporated into an organic phase by sol-gel to achieve a highly stable and anti-biofouling membrane for water treatment (Singh et al. 2012). Hybrid organic-inorganic nanostructured membranes have also found applications in the medical field for advanced separation of heavy metals from blood or other physiological liquids, such as new polymeric-carbon nanotube composite membranes based on polysulfone with different types of nanotubes (Nechifor et al. 2009). Another important area where these hybrid membranes may have a significant relevance is the energy sector, especially as new membranes for proton exchange membrane fuel cells (PEMFC) and solid-state Li-ion batteries. These membranes share several common characteristics, such as high ion conductivity (proton and lithium ion, respectively), low electronic conductivity, high thermal stability, and high chemical/electrochemical stability. Decreasing the membrane thickness but preserving the properties described above would improve the performance of the systems. Hybrid organic-inorganic nanostructured membranes can be designed to incorporate all these properties (Mosa and Aparicio 2012).

Hybrid Processes

Marco Scholz

Aachener Verfahrenstechnik – Chemical Process Engineering, RWTH Aachen University, Aachen, Germany

In membrane science, hybrid processes are processes, in which membrane technology is combined with conventional separation equipment to perform a separation more efficiently. The objective is to combine the positive characteristics of each individual technology to obtain a process which is better than the individual process.

Reverse osmosis, gas permeation, and in particular pervaporation are the most prominent membrane processes which are combined with conventional separation equipment to form hybrid processes (Melin and Rautenbach 2007). Conventional separation equipment is either limited by equilibrium and kinetics (e.g., amine) or by thermodynamic equilibrium only (e.g., cryogenic). However, the membrane separation is controlled by kinetics. Hence, combining both the equilibrium and the kinetic limited separation can have outstanding advantages. For instance, combining a distillation column and a pervaporation module is profitable as the pervaporation unit breaks the azeotrope and the bulk separation is performed by distillation.

Combining membrane technology and conventional separation technology can significantly reduce the equipment size. By applying hybrid processes, thermodynamic limitations can be overcome or more efficient processes can be designed regarding the capital as well as the operational costs.

There are many different process configurations, in which membranes and conventional

separation equipment can be combined. Depending on the process, membranes are applied for both, to perform the bulk separation and to polish the respective products. Hybrid processes are particularly interesting when membrane units are added to existing separation equipment. Hence, debottlenecking of processes or research activities can easily be performed without shutting down the separation process (Hömmrich and Rautenbach 1998).

Examples of Hybrid Processes

Skiborowski et al. analyzed a hybrid process in which seawater is desalinated (Skiborowski et al. 2012). Reverse osmosis modules are combined with forward-feed multi-effect distillation. For low energy costs, they identified the reverse osmosis network as the most profitable plant. For moderate energy costs and for high energy costs, the hybrid process and the multi-effect distillation are the optimal process configuration, respectively.

Baker and Lokhandwala investigated natural gas processing in detail (Baker and Lokhandwala 2008). Here, typically membrane technology and amine scrubbing compete. The carbon dioxide content in the feed gas and the feed gas flow rate determine which separation technology should be applied. Interestingly, for high carbon dioxide mole fractions and for high feed flow rates, the combination of membrane technology and amine absorption is the most efficient process configuration.

The vapor recovery of gasoline vapors from storage tanks can be done by applying rubbery gas permeation membranes and condensation equipment (Rautenbach et al. 1996). Here, the bulk separation is done by condensation and the gas is subsequently polished in a gas permeation unit. Both, the recovery of gasoline and environmental standards for the exhaust gas, have to be considered in the design of such a plant.

In the MTBE (methyl *tert*-butyl ether) production methanol, MTBE and *n*-C4 have to be separated. The separation is complex due to the formation of azeotropes (Hömmrich and

Rautenbach 1998). Two hybrid processes can be applied: one in which the mixture is fed to a pervaporation module to remove the methanol while the MTBE and the n-C4 fraction are separated in a distillation column. In the other process, the raw mixture is fed to a distillation column while the pervaporation module operates at a side draw. This latter hybrid process outclasses the conventional process, in which different distillation columns are applied.

Hybrid Regenerated Cellulose/Loaded Lipid Nanoparticle Membranes: Preparation and Characterization

Juana Benavente¹ and Juan Manuel López-Romero²

¹Departamento de Física Aplicada I, Universidad de Malaga, Facultad de Ciencias, Malaga, Spain

²Departamento de Química Organica, Universidad de Malaga, Facultad de Ciencias, Malaga, Spain

New membrane systems related to medical applications (drug-release devices, mimetic membranes, or patches) are receiving great attention

(Müller et al. 2000). Among them, lipid nanoparticles (LNPs) prepared using biocompatible components and with tunable properties are of significant interest (Gupta and Kompella 2006; Huynh et al. 2009); although, their use is still limited due to stability problems during contact with biological fluids, storage, or administration (Korting and Schäfer-Korting 2010). To overcome these limitations, polymeric nanosphere gels were proposed for topical delivery of lipophilic molecules (Martins et al. 2007). In this context, the inclusion of functionalized lipid nanoparticles (FLNPs) in support to biocompatible membranes (such as regenerated cellulose membranes) offers an attractive route for controlled release of pharmacologic agents.

The LNPs used in this study were prepared by the ultrasound method (Feng and Huang 2001) using L- α -phosphatidylcholine and Tween[®] 80 as surfactants and glyceryl tristearate as the main lipid component, while sunscreen DHB (2,4-dihydroxybenzophenone) was the active organic component. The hybrid membrane was obtained by embedding the DHBLNPs in a dense highly hydrophilic regenerated cellulose (RC) support by immersion in a water dispersion of DHBLNPs (membrane RC/DHBLNPs). The incorporation of the loaded LNPs was characterized by AFM, brilliant field microscopy (Fig. 1a), TEM (Fig. 1b), and Raman spectroscopy (Vázquez et al. 2011; Hierrezuelo et al. 2012). Reductions in material characteristic parameters (conductivity and dielectric constant) for dry RC/DHBLNP samples when compared with the original RC and changes associated to thermal effects were also obtained.

The stability of the hybrid membrane as a result of both contact time with NaCl solutions and osmotic pressure gradients was established by comparing diffusional permeability (Ps) for original RC and RC/LNP membranes (Vázquez et al. 2011; Hierrezuelo et al. 2012). The presence of the DHBLNPs reduces in approximately 20 % Ps values for the whole interval of feed concentrations studied ($0.001 \leq C_f(M) \leq 0.4$), and a constancy in the NaCl flow for at least 20 h was also observed. The cellulose structure also reduces the DHB delivery from the

Hybrid Regenerated Cellulose/Loaded Lipid Nanoparticle Membranes: Preparation and Characterization, Fig. 1 Hybrid membrane micrographs: (a) brilliant field microscopy (b) TEM

loaded LNPs, being the value for the hybrid membrane 5 % of that for the DHBLNPs (after 30 min).

Hybrid Silica Membranes

Toshinori Tsuru

Department of Chemical Engineering, Hiroshima University, Higashi-Hiroshima, Japan

A great deal of attention has been paid to silica membranes, which can accomplish separation tasks even under harsh conditions due to their high-separation performance, chemical inertness, and thermal stability (de Vos and Verweij 1998; Tsuru 2008). Two strategies have been proposed to prepare amorphous molecular sieving silica membranes: the sol–gel process and the chemical vapor deposition (CVD) method. Tetraethoxysilane (TEOS), which is a common Si precursor, has been widely adopted in both approaches, and the resultant membranes have been extensively investigated for gas separation, pervaporation, and membrane reaction. However, traditional TEOS-derived silica membranes suffer from poor hydrothermal stability, which greatly hampers their practical application. Inspired by the distinctive features of organic–inorganic hybrid silica materials with respect to flexibility, hydrothermal stability, and tunable pore sizes, researchers have concentrated on the preparation of hybrid silica membranes with improved hydrothermal stability and controlled pore sizes, using organoalkoxysilanes instead of TEOS.

Organic/inorganic hybrid membranes can be prepared either by the post-modification of hydrophilic ceramic membranes (Tsuru et al. 2004) or by the in-situ preparation using hydrophobic sols. In post-modification, hydrophilic porous membranes, the pore surface of which is covered with hydrophilic hydroxyl groups such as -SiOH , were modified with silane coupling agents such as trimethylchlorosilane in either a gas or a liquid phase, to convert the hydroxyl groups to a trimethylated surface. However, this method has several disadvantages; post-modification always reduces the effective pore sizes, leading to a decrease in flux. Moreover, it is difficult to modify membrane pores to less than several nanometers since the silane coupling agents cannot enter such small pores (Tsuru et al. 2004).

In-situ preparation of hydrophobic silica membranes was reported in sol-gel processing. Two typical kinds of organoalkoxysilanes have been used as Si precursors to prepare silica membranes via a sol-gel process. One is a bridged alkoxide, that is, a di-silicon alkoxide with a bridged group between the two silicon atoms, such as 1, 2-bis(triethoxysilyl)ethane(BTESE) $(\text{CH}_3\text{CH}_2\text{O})_3\text{SiCH}_2\text{CH}_2\text{Si}(\text{OCH}_2\text{CH}_3)_3$ and bis(triethoxysilyl)methane (BTESM) $(\text{CH}_3\text{CH}_2\text{O})_3\text{SiCH}_2\text{Si}(\text{OCH}_2\text{CH}_3)_3$ (Kanezashi et al. 2009; Castricum et al. 2008a, b). Castricum and coworkers (2008a; Castricum et al. 2008b) first reported on the BTESE-derived silica membrane and applied it to pervaporation dehydration of solvents of 95 wt% n-butanol-5 wt% water in an attempt to increase hydrothermal stability. The membrane was stable after 1.5 years, even though the test temperature was as high as 150 °C, while TEOS-derived silica membrane completely lost its separation ability within weeks at a much lower temperature of 95 °C. The excellent hydrothermal stability endowed by the organic-inorganic structures appears to be very promising for practical application. The formation of a looser structure and improved hydrothermal stability was due to the presence of a Si-C-C-Si minimum unit in the silica networks.

Another typical kind of organoalkoxysilane is a mono-silicon alkoxide with a pendant group, such as methyltriethoxysilane (MTES),

(trifluoropropyl)triethoxysilane (TFPTES), ethylenetriethoxysilane (ETES), or 3-methacryloxypropyltrimethoxysilane (MPS) (Raman and Brinker 1995; de Vos et al. 1999; Tsuru et al. 2011). Without burning out organic pendant groups, hybrid hydrophobic silica membranes could be obtained via the sol-gel process, which was first reported by de Vos et al. using TEOS and MTES as co-precursors (de Vos et al. 1999). The hybrid membranes prepared via this route also showed good hydrothermal stability and have been used for both gas separation and pervaporation. Considerable research on silica membranes prepared by mono-silicon alkoxides with pendant groups has led to a great deal of progress in understanding both the sol-gel process and the membrane characteristics.

Hydraulic Resistance due to Reversible Fouling

► Reversible Fouling Resistance

Hydrocarbon Branching

Arnaud Baudot

Physics and Analysis Division, IFP Energies nouvelles, Solaize, France

For more than 20 years now, regulations have imposed increasingly tight limitations on the content in gasoline of aromatic octane number boosters produced by the reforming of straight-run gasoline (alkanes). Among the available alternative technologies designed to enhance the octane number of straight-run gasoline, hydroisomerization is a catalytic technology that upgrades low-octane-number linear paraffins into higher-octane-number branched paraffins.

Since the rate of conversion of linear paraffins in the isomerization units is limited by a thermodynamic equilibrium, an option for increasing the production yield of dibranched paraffins consists of separating the linear and monobranched paraffins from the isomerization unit effluent and recycling them in the input of the isomerization reactor. The more conventional solution consists of fractionating the output stream from the isomerization reactor through a continuous distillation column (a deisohexanizer or DIH) into three effluents:

- A sidestream, mainly containing unconverted normal hexane and the monobranched paraffins with six carbon atoms. This stream is recycled to the isomerization unit.
- The bottom stream, containing the heaviest alkanes (paraffins) with six carbon atoms and naphthenes (cyclic paraffins) with six carbon atoms, with an RON of 82, is sent directly to the gasoline pool.

- At the top of the column, a head stream rich in dibranched paraffins with six carbon atoms, isopentane, and normal pentane. This stream, which corresponds to 90 % by weight of the fresh feed, has an RON (research octane number) of 87 though it contains about 16 % by weight of normal pentane, which has a low RON of 61.

With current distillation processes, it is not economically feasible to separate normal pentane from the other components in the top stream of the deisohexanizer since their respective boiling points are very close. This type of separation, however, can be achieved with molecular sieves, such as zeolites, implemented in cyclic adsorption processes such as a “simulated moving bed” (UOP Molex process) or “cycled pressurization/depressurization” (IFP IPSORB process or ExxonMobil ISOSIEVE process). With such processes, normal paraffins are preferentially adsorbed inside the microporosity of the zeolites and therefore separated from their branched isomers. Though offering excellent separation performance, this type of technology exhibits several drawbacks: high investment costs, sophisticated sequential operation (adsorption-desorption cycle), the use of large quantities of solvents (desorbants), and lack of modularity.

Since the beginning of the 1990s, much attention has been paid to overcoming the drawbacks of conventional zeolite adsorbents through the development of zeolite membranes that combine the technical advantages of membranes (modularity, continuous operation) with the high separation performances of zeolites (due to their sieving properties). Most of the published R&D work on that topic was carried out at lab scale mainly by academic laboratories, though a few companies, like *ExxonMobil* or *NGK Insulators*, have also published results on that topic. One of the most studied topics in this research field was the separation of normal short (C4–C6) paraffins from their branched isomers through MFI-type zeolite membranes (Arruebo et al. 2006; Bakker et al. 1996; Coronas et al. 1998). Indeed, MFI zeolites are crystalline aluminosilicates with a microporous structure that is composed of two intricate

micropore networks: elliptical straight channels with openings of 0.51×0.55 nm and zigzag channels that are almost cylindrical with a diameter of 0.53×0.56 nm, as measured by X-ray diffraction at ambient temperature (Flanigen et al. 1978). In such a confined porous system wherein the diameter of the micropores and the kinetic diameter of the diffusing molecules are close, the higher the kinetic diameter of a permeating molecule, the higher the friction of the molecule alongside the micropore wall and therefore the lower its diffusion coefficient inside the microporosity of the MFI zeolite. Therefore, the diffusion coefficient of normal alkanes in MFI zeolites is higher (Courthial et al. 2008) than the diffusion coefficient of their monobranched isomers. Moreover, these materials prove to be hardly permeable to dibranched paraffins. As an illustration, it was shown experimentally that a MFI zeolite membrane operated under close to industrial operating conditions (2–4 bar feed pressure, membrane temperature between 200 °C and 400 °C) was able to produce a permeate composed of 95 % normal pentane and 5 % isopentane from a vapor feed composed of 20 % 2,2-dimethylbutane, 55 % isopentane, and only 25 % normal pentane (Baudot and Bournay 2009).

Hydrogel

Hydrogels are cross-linked polymer systems able to retain large amounts of water by swelling. The presence in the polymeric chain of polar functional groups makes hydrogel hydrophilic systems; however, the cross-linking of the polymer matrix makes them insoluble in water (Fig. 1). The cross-linked structure can be achieved through two types of processes: chemical gelation and physical gelation. Gels with chemical bonds occur through the formation of covalent bonds among the structural units of the polymer chains and cross-linking agents (Peppas et al. 2006). The three main processes of chemical gelation are addition polymerization, condensation, and vulcanization. In contrast, the polymer chains in physical gels are connected via van der Waals forces, electrostatic attractions, and hydrogen bonds. Pectin, cellulose, agarose, collagen, and gelatin form physical gels.

Chemical and Physical Hydrogels

Initiation, propagation, and termination are the three steps of a polymerization process, i.e., the reaction among monomer molecules to form polymer chains or three-dimensional networks. During the first step of polymerization, a suitable amount of initiators, R , form by light irradiation or heat free radicals, R , which trigger the polymerization reaction as schematically shown in the following equation: $R \xrightarrow{h\nu/\Delta} R^\cdot$. These radicals can interact with a first monomer, M , and lead to the

Hydrogel, Fig. 1 (a) Structure of a hydrogel. $\overline{Mc}$ is the average molecular weight of chains between the crosslinks and ξ the average mesh size; (b) macroscopic

appearance of a hydrogel. The blue color is due to the ability of hydrogels to absorb both water and chemical compounds (in this particular case, methylene blue dye)

formation of monomers in propagation, $RM\cdot$, as shown in the following: $R\cdot + M \rightarrow RM\cdot$. Propagation consists in the growth of the polymer chain by the addition of monomers on the active site, as reported: $RM\cdots M\cdot + M \rightarrow RM\cdots MM\cdot$. Termination can halt propagation by either a disproportionation reaction or a combination reaction between two radical species.

There are different methods for the synthesis of physical gels: heating and cooling of polymer solutions (e.g., gelatin); ionic interactions (e.g., alginate); coacervation complexes by the interaction of polyanions with polycations, which form soluble complexes or insoluble depending on their concentrations and pH; hydrogen bonds, which lower the polymer solubility leading to the formation of elastic hydrogels (e.g., carboxymethyl cellulose); aging/maturation (e.g., arabic gum); and freeze-thaw. Gels with chemical bonds are provided by either polymerization of mixtures of monomers and cross-linkers or by cross-linking of preformed polymers. In the first method, a water solution of monomer, cross-linker, initiator, and catalyst is heated or irradiated to trigger the polymerization reaction. In the second method, preformed hydrophilic polymers are cross-linked by either the use of cross-linking agents (e.g., glutaraldehyde) or grafting, which functionalizes the polymer backbone with reactive species. Due to their three-dimensional structure and cross-linking centers, hydrogels swell rather than dissolve due to the diffusion of water molecules into

the polymer matrix. A polymer system initially free of water is defined as xerogel; the presence of hydrophilic groups and the degree of cross-linking establish the ability of the xerogel to store water. The greater the number of hydrophilic groups, the greater will be the ability to absorb water. The higher the degree of cross-linking, the lower the elasticity of the polymer network and the absorption of water.

Swelling Parameters

The degree of swelling is due to the equilibrium between the osmotic force, which favors the volume increase of polymer chains in the network, and the elastic forces arising from physical or covalent bonds present among the polymer chains. The swelling ratio, S_w , is a measure of how much water is retained by hydrogels and can be expressed as either the ratio between the weight of swollen gel at equilibrium, W_s , and the weight of dry gel, W_d , i.e., $S_w = W_s/W_d$, or the ratio between the volume of swollen gel at equilibrium, V_s , and the volume of dry gel, V_d , i.e., $S_v = V_s/V_d$. The percentage of swelling, $\%S_w$, is defined as $\%S_w = (W_s - W_d)/W_d \times 100$. As a function of their swelling behavior, hydrogels can be classified into conventional hydrogels, able to absorb water when they are inserted in an aqueous media, and their equilibrium swelling is not affected by environmental parameters and stimuli-responsive hydrogels, polymeric

networks which have a different equilibrium swelling in relation to environmental stimuli such as changes in pH, temperature, ionic strength, and electromagnetic radiation. In fact, every change in the water affinity of functional groups, such as a protonation or deprotonation due to a pH variation or a thermal change of hydration, leads to a reversible change in the degree of swelling. For example, the pH-sensitive hydrogels are widely used in the pharmaceutical field for administering active drugs irritating to the gastric mucosa or to protect an acid-labile substance from the stomach acid pH, i.e., the formulation is in a shrunk state at low pH and in a swollen state at high pH values. Hydrogels can withdraw solutes from aqueous solutions and can drop them in a controlled manner (Fig. 1b). It is possible to define the partition coefficient, K , as the ratio between the solute concentration in the gel (per unit volume of gel), C_{gel} , and the solute concentration in the aqueous solution in equilibrium with the external gel, C_{bulk} , i.e., $K = C_{\text{gel}}/C_{\text{bulk}}$. The changes in the hydrogel structure are often related to the average mesh size, ξ , which can be estimated by the Flory-Rehner theory (Peppas and Merrill 1977) according to the following equation:

$$\xi = v_{2,s}^{-1/3} \left(\frac{2C_n \overline{Mc}}{Mr} \right)^{1/2} l, \text{ where } C_n \text{ is the Flory characteristic ratio, } l \text{ the length of the bond along the polymer backbone, } Mr \text{ the molecular weight of the repeating units from which the polymer chain is formed, and } \overline{Mc} \text{ is given by } \frac{1}{\overline{Mc}} = \frac{2}{\overline{Mn}} - \frac{\bar{v}/V_1 [\ln(1-v_{2,s}) + v_{2,s} + \chi_1 v_{2,s}^2]}{v_{2,r} \left[\left(\frac{v_{2,s}}{v_{2,r}} \right)^{1/3} - \left(\frac{v_{2,s}}{2v_{2,r}} \right) \right]}, \text{ where } \bar{v} \text{ is}$$

the specific volume of polymer; V_1 is the solvent molar volume; χ_1 is the polymer-solvent interaction parameter; $v_{2,s}$ and $v_{2,r}$ are the polymer volume fraction in the swollen and relaxed states, respectively; and $\overline{Mn}$ is the molecular weight of the polymer chains prepared in the absence of cross-linking agent. The mesh size can be controlled by several factors, mainly by the water quantity before cross-linking and the amount and chain length of cross-linker. Both theory and experimental data show that by

increasing the amount of cross-linker compared to the quantity of monomer, there is a reduction of pore volumes and, consequently, of mesh sizes.

Applications

According to the particular application, hydrogels can be prepared as bulk systems, sheets, membranes, and nanoparticles (Nicoletta et al. 2012). There are several interesting applications of hydrogels in many fields including biochemical engineering, microelectronics, environmental science, agro-food and packaging, regenerative medicine and drug delivery, and gas separation. Examples of applications are:

1. Immobilization of enzymes. The immobilization is the restriction of enzyme mobility in a fixed space. This technique, compared to the use of enzymes in solution, has the advantage of making easier their recovery. The enzymes can be synthesized and reused reducing costs of manufacture; it is possible to optimize the microenvironment in order to increase the enzymatic stability and the product quality. The main methods for the immobilization of enzymes are adsorption (enzyme is linked on the surface of the substrate by physical bonds), retention on the support surface by covalent bonds, and entrapment (the enzyme solution is mixed with the prepolymer solution before the polymerization process).
2. Drug delivery systems (DDS). A drug delivery system is able to carry the drug in the body and control its release maintaining the plasma concentration within the therapeutic window. With a DDS it is possible to administer lower doses of drugs and limit side effects. As an example, polyacrylamide hydrogels were used as a DDS in the sustained release of insulin and delivery of other bioactive compounds. Molecular diffusion and carrier chemically controlled erosion are generally the major mechanisms of drug release.
3. Fillers in aesthetic and reconstructive surgery. The use of minimally invasive techniques is

now well known in plastic and cosmetic surgery. An ideal filler should be safe, effective, biocompatible, nonimmunogenic, easily obtainable, nonabsorbable, low-cost, and long term storable, properties that are fulfilled by many hydrogels, e.g., polyacrylamide is well tolerated in the subcutaneous tissue and glandular tissue in the breast. Another widespread application of hydrogel is the fabrication of contact lens for the most common ametropias or ocular drug release.

4. Wound synthetic dressing. Hydrogel dressing is able to create a moist environment around the wounds and facilitate wound healing, such as burns or necrotic wounds. Hydrogels can keep clean wounds by removing necrotic and infected tissues or by release of drugs. They are commercially available in sheet forms, plasters, gauzes, and gels that can be directly applied to wounds.
5. Membrane-supported hydrogels (Di Profio et al. 2014), which combine the general advantages of crystallization in gels (reproducibility, size increase, and mechanical stability of crystals) with those of membrane-assisted crystallization (process control, optimal conditions, reduced times, and specific targets). Membrane-supported hydrogels are excellent crystallization platforms as supersaturation is generated by gradual solvent removal in vapor phase through the porous structure of both membrane support and hydrogel layer. The beneficial effect of the gels, made from mixtures of acrylamide (monomer), poly(ethylene glycol dimethacrylate) (cross-linker), N,N,N',N'-tetramethylethylenediamine (catalyst), and photoinitiator, in crystallization processes by polypropylene membranes was confirmed on two model proteins, hen's egg white lysozyme and concanavalin A. By varying the ratio between monomer and cross-linker, it was possible to change the cross-linking degree and, consequently, the pore size tuning in the most adequate way the crystallization properties. Membrane-supported hydrogels were found to increase the efficiency of the crystallization process: crystals were produced at lower protein concentrations and with enhanced diffraction properties than conventional techniques.

Hydrogel Capsules

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Capsules are particles consisting of an inner core and a shell that covers and protects the core, prepared using polymeric hydrogels. Hydrogels constitute a three-dimensional network structure obtained from a class of synthetic and/or natural polymers which can absorb and retain significant amount of water. Water holding capacity, permeability, and biocompatibility are the most important characteristic property required by the hydrogel. The cross-links between the different polymer chains give a gel its structure (hardness) and elasticity and contribute to its stickiness. The hydrogel chemistry can be modified by controlling their polarity, surface properties, mechanical properties, and swelling behavior. Hydrogels can also be stimuli sensitive and respond to surrounding environment like temperature, pH, and presence of electrolyte (Nho et al. 2005). They can display changes in their swelling behavior of the network structure according to the external environments.

The main physical approaches used for hydrogel capsule manufacturing involve gelling

Hydrogel Capsules, Table 1 Cross-linking methods to produce hydrogels and types of polymer

Cross-linking method	Polymer
Physical cross-linking	
<i>Heating/cooling</i> Helix-formation, association of the helices, and junction zones formation Hot polymeric solution is cooled down	Gelatin, carrageenan
<i>Ionic interaction</i> Ionic polymers can be cross-linked by the addition of di- or trivalent counterions	Alginate, chitosan
<i>Complex coacervation</i> Complex coacervate gels can be formed by mixing of a polyanion with a polycation. Polymers with opposite charges stick together and form soluble and insoluble complexes depending on the concentration and pH of the respective solutions	Polyanionic xanthan with polycationic chitosan Gum arabic with gelatin
<i>H-bonding</i> H-bonded hydrogel can be obtained by lowering the pH of aqueous solution of polymers carrying carboxyl groups	Carboxymethyl cellulose
<i>Maturation (heat-induced aggregation)</i> Aggregation of the proteinaceous components, induced by heat treatment, increases the molecular weight and subsequently produces a hydrogel form with enhanced mechanical properties and water binding capability	Gum arabic
<i>Freeze-thawing</i> Microcrystals in the structure are formed due to freeze-thawing	Polyvinyl alcohol Xanthan
Chemical cross-linking	
<i>Chemical cross-linkers</i> Cross-linked chains are obtained by introducing new molecules (such as glutaraldehyde, epichlorohydrin, 1, 3-diaminopropane) between the polymeric chains	Polyvinyl alcohol Carboxymethyl cellulose
<i>Grafting</i> Polymer chains are activated by the action of chemical reagents, or high-energy radiation treatment. The growth of functional monomers on activated macroradicals leads to branching and further to cross-linking	Starch Polyvinyl alcohol
Radiation cross-linking	
Free radicals are produced in the polymer following the exposure to the high-energy source such as gamma ray, x-ray, or electron beam	Carboxymethyl cellulose Chitin, chitosan, and derivatives Starch and derivatives Alginate Hyaluronan and hyaluronic acid

the droplet phase of an emulsion or spray (Shewan and Stokes 2013). Emulsification can be used for many combinations of biopolymers and oils. Cross-linked networks of synthetic and natural polymers can be obtained by physical cross-linking, chemical cross-linking, grafting polymerization, and radiation cross-linking (Table 1). The physical cross-linking method is receiving an increased interest due to relative ease of production and the advantage of not using cross-linking agents. These agents affect the integrity of substances to be entrapped (e.g., cell, proteins, etc.) as well as the need for their removal before application. Radiation cross-linking is a widely used technique since it does not involve the use of chemical agents, therefore

retaining the biocompatibility of the biopolymer. Also, the modification and sterilization can be achieved in single step, and hence, it is a cost-effective process to modify biopolymers having their end use specifically in biomedical application.

Hydrogel capsules of many synthetic and natural polymers have been produced with their end use mainly in tissue engineering, pharmaceutical, and biomedical fields (Fernandez-Neives et al. 2011; Lima et al. 2012). Due to their high water absorption capacity and biocompatibility, they have been used in wound dressing, drug delivery, injectable polymeric systems, ophthalmic applications, and hybrid-type organs (encapsulated living cells).

Hydrogel Membranes

A membrane can be defined as a nanostructured/functionalized system which separates two different phases and can control the exchange of chemical species and energy between them. The transport is driven by the gradient of chemical potential and the application of external forces, and the flow is regulated by fluid and membrane properties. Hydrogel membranes are selective barriers made by cross-linked polymers able to retain large amounts of water by swelling (Peppas et al. 2006). They allow the flow of certain compounds (permeate) and retain some other compounds (retentate) present in fluid mixtures. Hydrogel membranes made by naturally derived (biologic) molecules have obvious biocompatibility, cell-controlled degradability, and intrinsic cellular interaction, but they may exhibit batch

variations and limited mechanical properties. In contrast, hydrogel membranes by synthetic polymers can be prepared with precisely controlled structures and functions. However, many synthetic polymers do not degrade in physiological conditions and have to be purified from eventually present toxic chemicals. Hydrogels are extremely useful in biomedical and pharmaceutical applications for their high water content and rubbery nature, which make them similar to natural tissue and with a high degree of biocompatibility. Hydrogels can protect drugs from hostile environments, such as enzymes and low pHs. Drugs loaded into the gel matrix can be released at a predesigned rate in a desired site. The mechanism of drug release from hydrogels is generally passive diffusion of molecules, which freely diffuse out of the hydrogel matrix, but is possible to control the drug release by changing the gel structure in response to environmental stimuli, such as pH, temperature, ionic strength, and electric/magnetic field.

Tissue Remediation

In addition to drug delivery applications, hydrogel membranes are also relevant in tissue engineering and remediation, i.e., for repairing and regenerating a wide variety of tissues and organs. Hydrogel dressing is a modern synthetic dressing of wounds. Its essential characteristics are the rehydration of tissues, the cleaning of wounds by removing necrotic and infected tissues, the delivery of drugs, and the maintenance of a moist environment in order to facilitate the healing of wounds, such as burns, necrotic sores, and open and chronic wounds. Such dressings are available in a variety of forms and shapes, such as sheets, pads, and gels that can be directly applied to wounds. Commercially available hydrogel sheets do not need a secondary dressing and can be cut to fit around the wounds. Hydrogel dressings do not stick to wounds and, consequently, can be easily removed, causing less pain during changes and increasing the compliance of patients and, in particular, of children. In the field of tissue engineering, hydrogels are used as a scaffold

material for the growth and replacement of various tissues as they structurally resemble the extracellular matrix of the human body. Other applications of hydrogels include tissue-engineered matrices for skin replacement and non-load-bearing bone tissue engineering, i.e., artificial skin grafts, cartilage tissues, and tissue-engineered products. Hydrogel membranes can be prepared with different mesh sizes in order to modulate their transport properties such as flux and selectivity. Mesh size can be varied by changing material concentrations, and, in particular, the amount of cross-linking agent. Thanks to its resistance to protein adsorption, biocompatibility, and non-immunogenicity, poly(ethylene glycol), PEG, plays a significant role as a hydrophilic polymer for the preparation of hydrogel membranes used in regenerative medicine. PEG has a chemical structure which can be converted into other functional groups (methyloxyl, carboxyl, acetylene, amine, azide, vinyl sulfone, thiol, and acrylate) for conjugation of biomolecules. Cross-linked PEG hydrogels can be obtained by free radical photopolymerization of PEG acrylates, Michael-type addition, native chemical ligation, and enzymatic reaction. Among these approaches, the synthesis of PEG hydrogels through photopolymerization is the most common approach which uses light to convert PEG prepolymer solutions into cross-linked insoluble hydrogels. The major type of macromers used for photopolymerization includes PEG diacrylates, multiarm PEG acrylate, and PEG dimethacrylate. PEG hydrogels can be modified to be degradable through incorporation of degradable segments, such as polyester, polypropylene fumarate, acetal, and disulfide.

Photoresponsive Hydrogel Membranes

The category of responsive membranes hosting reactive functions includes several systems such as flat and hollow fiber membranes, nanocomposite layers, microcapsules, switchable interfaces, core-shell structures, and free-standing hydrogels. Typical photoreactive groups in polymers are azobenzene, triphenylmethane, and

spiropyran, which can be entrapped, cross-linked, or introduced as a side chain or part of the main chain in polymer matrices (Nicoletta et al. 2012). Upon irradiation with UV-Vis light, the conformational changes of the photoreactive groups result in photoinduced effects on hydrogel matrix: pore average size changes as a consequence of expansion and contraction of the photoreactive groups. Some applications include the control of ion permeation through membrane gates (a kind of light-valved membranes that change the permeability of ions under UV irradiation) and light-controllable microfluidics. In fact, as hydrogel membranes expand in response to environmental conditions such as pH, temperature, photoirradiation, or solvent, they can facilitate the permeation of solutes, while their shrinking can suppress permeation. In particular, hydrogel brushes cast on porous membranes can open or close pores in response to environmental stimuli. An interesting application is the polyacrylamide hydrogel containing bis-[4-{dimethylamino}phenyl]{4-vinyl-phenyl} methyl leucohydroxide, which has been studied as photoresponsive and ion-selective membrane. Upon irradiation, the production of photocations increased the transport of anionic species, but had no effect on neutral species.

Membrane-Supported Hydrogels

Crystallization is, today, a fundamental operation in industry, especially pharmaceuticals, health care, and biotechnology. Efficiency, simplicity, flexibility, selectivity, permeability, compatibility, economy, stability, eco-friendship, control, and scale-up are some characteristics of membrane operations, which are important tools for the preparation, separation, crystallization, and purification of chemicals. Membrane-assisted crystallization, or shortly membrane crystallization, is an innovative technology, which allows crystal nucleation and growth under more uniform and predictable conditions favoring, in particular, compound purity, polymorphic selectivity, crystal size, and process upscale. Membrane-assisted crystallization improves significantly product characteristics and enhances process efficiency with less waste, energy, and resources. Costs are

Hydrogel Membranes,

Fig. 1 Scanning electron microscope image of a membrane-supported hydrogel. A hydrogel layer is polymerized on a porous membrane of polypropylene. Unit bar is equal to 10 μm

reduced consequently. An interesting approach is represented by membranes in combination with functionalized layers of hydrogels. This strategy includes the use of porous polymeric membranes and their functionalization with a thin hydrogel layer with an opportune mesh size (Peppas and Merrill 1977) and specific chemical composition. Cross-linked hydrogels have shown their ability to concentrate solute molecules via thermodynamic partitioning driven by favorable polymer-solute interactions. Gels generally give rise to crystals with greater sizes, fewer defects, and enhanced diffraction properties than crystals grown in solution because of the suppression of convection currents, sedimentation, and reduced random collisions between molecules. Nevertheless, the main drawback of gels is their handling difficulty, which can be passed by using adequate supports such as a membrane. In fact, earlier researches on membrane-supported hydrogels were mainly related to gel-filled pore membranes with the aim of enhancing mechanical stability, modulating transport of specific components as sketched in section “[Photoresponsive Hydrogel Membrane](#)” and reducing fouling. More recently, the possibility to fabricate membrane-supported hydrogel displaying controlled chemical composition and nanostructure to combine the general advantages of crystallization in gels (reproducibility, size increase, and mechanical stability of crystals) with those of membrane-assisted crystallization (process control, extended

optimization, reduced times, and specific targets) (Di Profio et al. 2014) has been shown. Membrane-supported hydrogels were found to be excellent crystallization platforms in which supersaturation is generated by gradual solvent removal in vapor phase through the porous structure of both membrane support and hydrogel layer (Fig. 1). The beneficial effect of the gels, made from mixtures of acrylamide (monomer), poly(ethylene glycoldimethacrylate) (crosslinker), N,N,N',N'-tetramethylethylenediamine (catalyst), and photoinitiator in membrane crystallization, was confirmed on two model proteins, chicken hen egg white lysozyme and concanavalin A. By varying the ratio between monomer and crosslinker, it was possible to change the cross-linking degree and, consequently, the pore size tuning in the most adequate way with the crystallization properties. Membrane-supported hydrogels were found to increase the efficiency of the crystallization process: crystals were produced at lower protein concentrations and with enhanced diffraction properties than conventional techniques.

Hydrogel Nanoparticles

Hydrogel nanoparticles are nanometer-sized particles composed of cross-linked hydrophilic polymer networks (hydrogels) (Lyon and Serpe 2012; Peppas et al. 2006). They are also known as nanogels, where the term nano refers to materials, one dimension of which is less than 100 nm. The very low dimensions of nanomaterials confer them physical–chemical properties which can differ from those of the same bulk materials. As all other nanoparticles, nanogels are characterized by a high surface/volume ratio which gives them larger activities in surface-related phenomena

(e.g., adsorption, reaction rates, etc.) than hydrogel membranes. Consequently, there has been a very rapid spread of nanoparticles in many fields of daily life including fillers, cosmetics, catalysts, pharmaceuticals, sensors, lubricants, electronic devices, actuators, waste (dyes, heavy metals, and organic pollutants) remediation, advanced materials, regenerative medicine, and imaging tools (Chidichimo et al. 2013). Stimulus-responsive nanogels offer the opportunity to develop systems for applications in particular fields, such as drug delivery, biological sensing, and separation and purification technologies, thanks to their ability to undergo reversible volume phase transitions in response to environmental stimuli, such as pH, temperature, ionic strength, solvent quality, enzymes, and external electromagnetic fields (Fig. 1; Nicoletta et al. 2012). Nanogels are obtained by chemical or physical cross-linking of either synthetic or natural polymers and can be swollen/shrunk in the presence/absence of water or under the change of environmental conditions. Nanogels can be filled with molecules which can be released in opportune sites depending on the swelling/shrinking properties of nanoparticles, the erosion/degradation of polymer networks, and the reaction of chemical groups to external stimuli. These properties promote nanogels as the major carrier of drugs and contrast agents in human body. Nowadays researchers are interested in the synthesis of new hydrogel nanoparticles for applications as drug delivery systems, thermosensitive capsules, and carriers of agents for therapy and diagnostics. The main drawbacks for the use of hydrogels in many applications are the gel shrinking/swelling speed and mechanical strength. The formation of a skin layer at the very initial stage of gel shrinking

Hydrogel Nanoparticles,

Fig. 1 Volume phase transitions in nanogels in response to an external stimulus

lowers shrinking rate as it reduces the water diffusion from inside the gel to the external environment. Possible solutions to these drawbacks are the synthesis of new monomers, the modification of polymer chains (e.g., by grafting), and the use of additives (plasticizers, fillers, chemical catalysts, retarders, surfactants, etc.) in monomer solutions. In addition to nontoxicity, the response of a tissue to gel material is an important item that has to be tested carefully. In fact, different tissues (subcutis, arteries, tendons, muscles, nerves, etc.) can respond in a different way to the contact with polymer and induce its degradation with time. Other goals in nanogel research are the integration of multiple functions, the sensitivity to different stimuli, and a better control of responses. Hybrid hydrogel nanoparticles are nanometric particles with their surface properties modified by cross-linked hydrophilic polymer networks (hydrogels) in order to increase efficiency and selectivity toward particular functions or *stealth* nature of nanoparticles to the reticuloendothelial system or macrophage system.

Chemically and Physically Cross-Linked Nanogels

Nanogels can be classified as either chemically cross-linked nanogels or physically cross-linked nanogels. Chemically cross-linked nanogels are formed by cross-linking of polymers via covalent bonding. In contrast, noncovalent bonds (i.e., hydrogen bonds, ionic bonds, and hydrophobic interactions) link polymers in physically cross-linked nanogels. The most common approaches for the preparation of responsive nanogels are (i) emulsion polymerization and (ii) physical self-assembly of polymers. Emulsion polymerization generally allows controlling size, stability, and surface properties of nanogels. It involves the emulsification of hydrophobic/hydrophilic monomers in water by an oil-in-water/water-in-oil emulsifier and the initiation of reaction with either a water- or oil-soluble initiator (oil/water or water/oil emulsions). Water-in-oil emulsion polymerization is the best technique for water-soluble monomers: an aqueous solution of monomers is

mixed to the oil phase and surfactant to give thermodynamically stable micelles. Polymerization is initiated by initiators either in the aqueous phase or in the oil phase. In both oil-in-water and water-in-oil emulsion polymerization, the size of the nanogels can be controlled by varying the amount of surfactant. Smaller nanogels can be obtained by higher surfactant concentrations. However, surfactants used in emulsion polymerization have to be removed at the end of the polymerization reaction by dialysis or desorption, with possible coagulation or flocculation of nanoparticles. A way to solve this problem is the use of surfactant-free emulsion polymerization. Noncovalent interactions, such as hydrogen bonds, van der Waals forces, and electrostatic and hydrophobic interactions, allow preparing nanogels. A physical self-assembly of interactive polymers consists in amphiphilic block copolymers that self-assemble into micelles via noncovalent interactions. During the self-assembly process, small active molecules can be incorporated into the nanostructures. Nanoparticle size can be tailored by changing the block nature, block lengths, and copolymer composition. In addition, the change of other parameters, such as temperature, solvent, and additives, allows tuning the properties of aggregates. In particular, surface modifications and core functionalities of nanogels can allow the recognition of specific cells and an improved drug encapsulation. However, it is difficult to obtain stable physically cross-linked nanogels with controlled sizes using noncovalent interactions because the bonds are relatively weak.

Responsive Nanogels

A responsive nanogel is a nanoscopic three-dimensional gel network consisting of cross-linked macromolecular chains that can undergo volume phase transitions in response to an external stimulus. The thermally induced swelling or shrinking of a nanogel is caused by the thermally driven coil-to-globule transition of polymer chains (conformational change) between two neighboring cross-linking points inside the gel

network. Thermally sensitive charged nanogels can be used in protein adsorption and separation as they can form with protein complexes with a core-shell structure characterized by different properties. Interesting monomers for the synthesis of thermally responsive nanogels are those with a lower critical solution temperature in water around that of human body for their obvious applications as drug delivery systems. Poly (N-vinylcaprolactam)-based gels have a volume phase transition temperature around 33–34 °C, which can be modified by copolymerization of N-vinylcaprolactam with other monomers. In fact, copolymerization changes the hydrophilic/hydrophobic balance of the resulting polymer and consequently its critical solution temperature. In addition, copolymerization of N-vinylcaprolactam with monomers/cross-linkers allows tuning the chemical structure, size, charge, and swelling degree of nanoparticles. The biocompatibility and solubility in water solutions make poly (N-vinylcaprolactam)-based gels suitable for biomedical applications. Unlike the densely packed nanocarriers usually used for drug delivery systems, nanogels can bind within their networks a large amount of water molecules and bioactive compounds including drugs, proteins, and DNA in a relatively stable manner. These compounds can be released by the gel structure changes occurring during the volume phase transition.

Alkali-swellable nanogels containing carboxylic acids display extreme pH sensitivity and rheological changes in water. In fact, the neutralization of such aqueous dispersion causes the swelling of the nanogels with a consequent dramatic increase in viscosity and shear thinning of the dispersion. On increasing pH, the swelling increases due to the ionizing of carboxylic acid groups. In addition, the increase in ionic strength screens the internal repulsion or reduces the osmotic pressure difference between inside and outside of the nanogel particles.

Hydrogen from Bioethanol

Jose M. Sousa

Chemistry Department, School of Life and Environment Sciences, University of Tras-os-Montes e Alto Douro, Vila Real, Portugal

LEPABE – Laboratory for Process Engineering, Environment, Biotechnology and Energy, Chemical Engineering Department, Faculty of Engineering, University of Porto, Rua Roberto Frias, Porto, Portugal

The production of hydrogen from bioethanol has been considered an attractive way for exploring sustainable renewable energy sources, from an environmentally friendly point of view. Bioethanol consists of an aqueous solution containing 8–12 wt.% of ethanol, besides other by-products such as glycerol, acetaldehyde, diethyl ether, methanol, etc. (Ni et al. 2007; Iulianelli and Basile 2011).

Hydrogen production from ethanol is essentially carried out by steam reforming, according to the main reaction described by $C_2H_5OH + 3H_2O \rightarrow 6H_2 + 2CO_2$, $\Delta H(298K) = 348 \text{ kJ} \cdot \text{mol}^{-1}$. Ethanol steam reforming is a very attractive way to locally produce hydrogen, comparatively to other fuels such as methanol, glycerol, acetic acid, diethyl ether, etc. For example, ethanol is easily obtained by fermentation from renewable sources such as sugars and starches (e.g., sugarcane and corn – first-generation bioethanol) and

from lignocelluloses (agricultural, industrial, and forest residues – second-generation bioethanol), among other sources; ethanol is easy to transport and store, it is biodegradable and shows low toxicity; ethanol is relatively easy to dehydrogenate by steam reforming, and it does not contain catalyst poison such as sulfur (Ni et al. 2007).

Steam reforming of ethanol is a highly endothermic reaction, which limits its industrial application for hydrogen production. The oxidative reforming, oxidation of a fraction of ethanol to provide part of the energetic needs, is a possible way to minimize such impact. If the amount of oxygen is sufficient for balancing the reforming enthalpy needs, the process is named autothermal reforming (Song 2012). Other ways to produce hydrogen from ethanol are fermentation processes using metabolically engineered microorganisms, solar photocatalytic processes using suitable semiconductors, CO₂ dry reforming, plasma reforming, partial oxidation, and aqueous phase reforming (Song 2012).

Concerning the catalysts for the hydrogen production from (bio)ethanol, current state of the art includes the noble metal-based (Pt, Pd, Ru, Rh) and non-noble metal-based (Cu, Co, Zn, Ni) ones (Iulianelli and Basile 2011). The ethanol conversion and hydrogen yield and selectivity are strongly dependent on the catalyst type, its support (e.g., ZnO, MgO, Al₂O₃, SiO₂, La₂O₃, CeO₂), and the reaction conditions (Costa-Serra et al. 2010; Song 2012).

Besides the ethanol steam reforming main reaction referred above, the process follows a complex reaction system with several possible consecutive parallel reactions, such as partial reforming to CO, water gas shift, methanation, coke formation from intermediate products, Boudouard reaction, CO reduction, methane cracking, dehydration/hydrogenation, and

dehydrogenation. In addition to H₂ and CO₂, reformat stream may contain also CO, methane, aldehydes, ketones, ethylene, ethane, and high alcohols, among others (Vizcaíno et al. 2007; Song 2012) (Fig. 1).

The main drawback of using bioethanol to produce hydrogen via steam reforming is the high cost associated to the downstream distillation and purification steps of the crude ethanol obtained from fermentation. Feeding directly the crude bioethanol to the reformer would reduce drastically the costs of the produced hydrogen. Besides the unnecessary expensive distillation process for water and other compounds elimination, the reforming of other oxygenated hydrocarbons contained in the fermentation broth could contribute to generate extra hydrogen. The main challenge for the implementation of this approach at an industrial level remains in the tolerance and stability of the catalyst to the impurities present in the crude ethanol solution, especially high linear and branched alcohols (Le Valant et al. 2011; Song 2012).

In the viewpoint of hydrogen production for supplying polymer electrolyte membrane fuel cells (PEMFCs), the reformat stream, which comprises a complex mixture of compounds, needs a separation/purification, especially due to the maximum allowed CO concentration (0.2 ppm). A conventional steam reformer system is composed by the reformer (fixed bed reactor (FBR)), two water gas shift reactors (high- and low-temperature WGS), a CO partial oxidation reactor (PROX), and pressure swing adsorption (PSA) units (Fig. 2).

This complex process may be replaced by a much simpler membrane reactor (MR) holding hydrogen permselective membranes. This new reactor is able to perform both the steam reforming of bioethanol and the separation/

Hydrogen from Bioethanol, Fig. 2 High-purity hydrogen production in a conventional multistage system

Hydrogen from

Bioethanol, Fig. 3 High-purity hydrogen production in a membrane reactor with a Pd-based membrane

purification of the produced hydrogen in the same device (Fig. 3).

Moreover, this kind of MR makes possible the in situ removal of hydrogen from the reaction side, allowing the conversion to overcome the thermodynamic equilibrium value (which is not possible in the FBR). Furthermore, if Pd or Pd-based membranes are used, a pure hydrogen stream is collected in the permeate side, suitable for direct PEMFC supplying (Iulianelli and Basile 2011).

Hydrogen Production by Membrane Reactors

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Hydrogen, the energetic vector of the future, is expected to become more and more important according to leading energy scenarios as also reported in the EU-White Paper (http://ec.europa.eu/research/energy/pdf/efchp_hydrogen13.pdf) on renewable and alternative energy. Moreover, BP and GE announced plans to develop jointly up to 15 new hydrogen power plants to generate electricity over the coming decade (http://www.bp.com/content/dam/bp/pdf/investors/BP_Annual_Report_and_Form_20F_2014.pdf). The hydrogen required is planned to be derived from fossil fuels, including coal and natural gas, while developing, in the meantime, new plants equipped for carbon capture technologies capable of reducing CO₂ emissions by 90 % (<http://www.worldwatch.org/node/4516>). If one considers that, at present, 96 % hydrogen is directly produced from fossil fuels and ca. 4 % indirectly by using electricity generated through them (Kothari et al. 2008), the need to find new efficient and competitive technologies able to maximize hydrogen production

from fossil fuels while lowering CO₂ emissions and other pollutants appears evident.

In addition, up to now, steam is utilized for most H₂ obtained industrially from natural gas or light hydrocarbons. Conventional technologies can also operate with alternative fuel sources such as, for instance, bioalcohols and other biomasses, having attracted great attention owing to their being renewable sources (Abanades et al. 2013; Vizcaino et al. 2012; Sanz et al. 2014; Iulianelli et al. 2014). Along with these technologies, which can be integrated with CO₂ separation units, membrane reaction and separation units are becoming more and more promising and significant in hydrogen production. Membrane reactors couple conversion and separation in the same operating unit and this leads to a conversion higher than the thermodynamic one of conventional reactors, a lower reaction volume, a pure (permeate) hydrogen stream, and a concentrate in CO₂ (retentate) stream. The permeate hydrogen stream has a pure grade that can be directly fed without any further treatment to a polymeric electrolyte membrane fuel cell and no performance loss is observed (Brunetti et al. 2008).

Thus, the new model reactor has several advantages with respect to conventional technology, i.e., the production of a new carrier and CO₂ capture, since pure hydrogen and CO₂ concentrated streams exit this reactor.

Membrane reactors can operate in various sections of the hydrogen production plants: replacing both steam reforming (SR) as well as high- and low-temperature water gas shift (WGS) reactors.

Steam reforming is the reaction between hydrocarbons and water vapor. The steam reforming of methane is the best known of this reaction class owing to its industrial importance in hydrogen and syngas production (Scholz 1993). A methane steam reformer is industrially operated at 700–1100 °C and 20–30 bar over Ni-based catalyst; the main species and reactions involved are (Xu and Froment 1989a, b)

High temperature and low pressure thermodynamically favor the process because the reaction is endothermic and also characterized by an increase in the number of moles. This reaction is thermodynamically limited and the selective hydrogen removal will increase its conversion.

The development of ceramic and supported metallic (e.g., palladium-based) membranes has promoted the investigation of the membrane reformer for a high-temperature reaction. Dense palladium-based membranes are characterized by infinite hydrogen selectivity which prevents the permeation of other species through the metallic structure of the palladium.

The operating conditions (temperature, pressure, flow rate, composition, etc.) have to be completely rethought since the permeation significantly affects the reforming process/reaction.

Methane steam reforming can be operated at a significantly lower temperature (400–500 °C) since the reaction pressure favors hydrogen permeation. The higher the feed pressure, the higher the hydrogen removal and as a consequence the methane conversion (see Fig. 1).

The stream produced by reformers and/or coal gasification plants contains around 50 % molar of hydrogen (on a dry basis) and between 40 % and 45 % molar of CO, which is usually reduced in an upgrading stage producing more hydrogen at the same time, by WGS reaction. The upgrading stage of traditional processes consists of a multistage CO-shift process based on two catalytic reactors: the first operates at high temperatures (about 350–400 °C) to take advantage of the faster reaction rates, whereas the other operates at low temperatures (around 220–300 °C) to refine the carbon monoxide conversion, thus allowing a lower final CO concentration (less than 1 % molar) (Raggio et al. 2005).

Hydrogen Production by Membrane Reactors, Fig. 1 Equilibrium conversion of Methane as function of the temperature for both membrane and traditional reactors at different feed pressure values for $\text{H}_2\text{O}/\text{CH}_4$ initial ratio of 3. For membrane reactor, the permeate pressure is 1 bar and the sweep contained in the permeate chamber is the times higher than the methane amount in the reaction volume. (Marigliano et al. 2001, 2003)

$$\Delta H_{298}^0 = -41 \text{ kJ mol}^{-1}$$

The H_2 -rich stream coming out from the last reactor is fed to a pressure swing adsorption (PSA) unit for H_2 separation from other gases. Most often another reaction unit is added for oxidizing CO to CO_2 , to meet the purity targets for fuel cell uses (CO concentration lower than 10–20 ppm). Additionally, the reduction of the percentage of CO in the system reduces coking of metal catalyst surfaces, implying a longer lifetime. This means an intensified process with a reduced plant size and a higher yield. In some cases, the interesting results achieved at laboratory level thanks to this effect have even led to several patents (Deckman et al. 2005; Gummalla et al. 2010; Lamm et al. 2005; Tsay et al. 2007; Wei 2009; Willms and Birdsell 2000).

However, most of the studies on WGS in MRs were carried out in a low and medium temperature range (180–250 °C and 250–320 °C, respectively) by using CuO-based catalysts, owing to the

thermodynamics constraints on the reaction (Barbieri et al. 2008; Dittmeyer et al. 2001; Mendes et al. 2010, 2011; Paglieri and Way 2002; Pinacci et al. 2010). Only few works in the literature have explored the combination of a high-temperature WGS catalyst with Pd-based membranes (Augustine et al. 2011; Bi et al. 2009; Brunetti et al. 2012, 2015; Catalano et al. 2013; Chein et al. 2013; Iyoha et al. 2007; Pinacci et al. 2010; Uemiya et al. 1991). An interesting review on the recent advances of this technology for high-temperature applications is proposed by Cornaglia et al. (2015).

Rather than the limitations of thermodynamics, fast kinetics and promoted permeation are the main advantages offered by the high temperature. However, a fundamental role is played by the characteristics of the membrane used in the reactor. In fact, until now one of the main hurdles limiting the large-scale development of these MRs is the high cost of Pd-based membranes, partly owing to the cost of palladium that could further increase if Pd membranes are exploited on a large industrial scale (Helmi et al. 2014). For this reason, great efforts are being made to obtain thin Pd layers on appropriate supports in order to maximize the permeate flux, minimize the support influence, and reduce the cost related to Pd (PachecoTanaka et al. 2005; Zhang et al. 2009).

Hydrogen Production by Water Splitting

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

Hydrogen is a promising energy vector in many industries such as metallurgical industry, thermal treatments, petrochemical industry, food industry, electrical energy production, electronic industry, and mechanical industry because of the zero environmental impact of the combustion products (only water). Main sources of hydrogen are fossil (reforming of petroleum, reforming of natural gas, carbon gasification) and nuclear thermochemical and renewable processes (electrolysis from eolic and photovoltaic electrical energy, solar thermochemical processes, biomass gasification). Steam reforming of hydrocarbons is the dominant technology, but today an interesting renewable source for hydrogen production is water splitting. The theoretical energy to split water to produce H₂ and O₂ (e.g., under solar light) is

$$\Delta G = 237 \text{ kJ mol}^{-1}$$

Energy for water splitting can be supplied by various processes such as electrolysis, photochemical, photocatalytic, and thermal decomposition.

Photocatalytic water-splitting technology using nano-sized TiO₂ has great potential for low-cost, environmentally friendly solar-hydrogen production to support the future

hydrogen economy (Fujishima and Honda 1972). Presently, the solar-to-hydrogen energy conversion efficiency is too low for the technology to be economically sound. The main barriers are the rapid recombination of photo-generated electron/hole pairs and the backward reactions and the poor activation of TiO₂ by visible light (only 3–5 % of photons present in the solar light can photoactivate it). In response to these deficiencies, some investigators studied the effects of addition of sacrificial reagents and carbonate salts to prohibit rapid recombination of electron/hole pairs and backward reactions. Other research focused on the enhancement of photocatalysis by modification of TiO₂ by means of metal loading, metal ion doping, dye sensitization (O'Regan and Grätzel 1991), composite semiconductor, anion doping, and metal ion implantation. Metal ion implantation and dye sensitization are very effective methods to extend the activating spectrum to the visible range. Therefore, they play an important role in the development of efficient photocatalytic hydrogen production (Ni et al. 2007). The metal ion-implanted TiO₂ could efficiently work as a photocatalyst under visible light irradiation. Some field tests under solar light irradiation clearly revealed that the Cr ion- or V ion-implanted TiO₂ samples showed 2–3 times higher photocatalytic reactivity than the un-implanted TiO₂. Instead, a visible light-responsive TiO₂ thin-film photocatalyst, developed by a single process using a radio frequency magnetron sputtering (RF-MS) deposition method, showed high photocatalytic reactivity for various reactions such as reduction of NO_x, degradation of organic compounds, and splitting of H₂O under visible and/or solar light irradiations (Takeuchi et al. 2012). Cation- or anion-doped metal oxides or metal oxynitride was used to prepare visible light-responsive TiO₂ thin films by a radio frequency magnetron sputtering method that were applied for the separate evolution of H₂ and O₂ from water under visible or solar light irradiation (Matsuoka et al. 2007). A photochemical water-splitting system, composed by two reactors divided by a proton-conducting membrane in which photocatalytic half reactions of water reduction and water oxidation took place, was proposed by

Zamfirescu et al. Complex molecular devices based on ruthenium(bipyridine)(3)(2+) photosensitizers were dissolved in both reactors, which generate electrons or holes when exposed to high-energy photonic radiation, and acted as catalysts for water splitting. These molecular devices for water reduction have a unique property to enhance the existence time of photoelectrons, such that the likelihood of generated electron pairs to produce a molecule of hydrogen is increased (Zamfirescu et al. 2011). Thermochemical cycles using water as raw material and nuclear/renewable energies as sources of energy are believed to be a safe, stable, and sustainable route of hydrogen production. Among the well-studied thermochemical cycles, the sulfur-iodine (S-I) cycle is capable of achieving an energy efficiency of 50 %, making it one of the most efficient cycles among all water-splitting processes (Kar et al. 2012).

The S-I cycle is characterized by three basic reactions as shown below:

1. $\text{I}_2 + \text{SO}_2 + 2\text{H}_2\text{O} \rightarrow 2\text{HI} + \text{H}_2\text{SO}_4$ (120 °C)
2. $2\text{H}_2\text{SO}_4 \rightarrow 2\text{SO}_2 + 2\text{H}_2\text{O} + \text{O}_2$ (830 °C)
3. $2\text{HI} \rightarrow \text{I}_2 + \text{H}_2$ (450 °C)

In order to overcome the low efficiency due to the poor equilibrium decomposition of HI in the third reaction, ongoing research is dedicated toward the development of a hydrogen-permselective membrane reactor. Proper identification of suitable membranes (e.g., asymmetric silica membrane) and introduction of membrane reactor is proposed to improve the efficiency of the overall cycle and make hydrogen production more economical. The challenges are associated toward the development of a membrane reactor which can be applied in highly corrosive environment like HI under a high temperature of about 500 °C (Kar et al. 2012). Perovskites are investigated as potential redox catalyst materials for the thermochemical production of hydrogen where water is dissociated giving rise to the production of pure hydrogen during the oxidation step. The oxidation and reduction steps can be combined in a membrane reactor constructed from dense

perovskite membranes toward a continuous and isothermal operation. At steady state and 900 °C, $25 \pm 7 \text{ cm}^3_{(\text{STP})\text{H}_2} \text{ m}^{-2} \text{ min}^{-1}$ is produced in purified state (Nalbandian et al. 2009). In a perovskite hollow-fiber membrane, the oxygen permeation flux increased 3.5 times more than that of the blank membrane when feeding reactive CH_4 onto the permeation side of the membrane. The membrane was used as a reactor to shift the equilibrium of thermal water dissociation for hydrogen production because it allows the selective removal of the produced oxygen from the water dissociation system. It was found that the hydrogen production rate increased from 0.7 to $2.1 \text{ mL}_{\text{H}_2} \text{ min}^{-1} \text{ cm}^{-2}$ at 950 °C after depositing a perovskite Pd porous layer onto the perovskite membrane (Jiang et al. 2010).

Hydrogen Removal by Membranes

V. V. Volkov

A.V. Topchiev Institute of Petrochemical
Synthesis Russian Academy of Sciences
(TIPS RAS), Moscow, Russian Federation

Pure hydrogen is known to be a valuable industrial material, and its annual consumption comes to billions of cubic meters. Over 90 % of hydrogen is generated from fossil fuel sources (mainly, steam reforming of natural gas) and the other 10 % is produced by water electrolysis. Hydrogen is widely used in diverse large-scale processes in metallurgical, chemical, petrochemical, pharmaceutical, and textile industries for the production of a wide range of products – from semiconductors and steel alloys to vitamins and raw chemical materials such as ammonia, methanol, and hydrogen peroxide. Recently, hydrogen has attracted a keen attention as an alternative energy carrier for the solution of environmental problems (so-called concept of “hydrogen economy”). In contrast to fossil fuels, hydrogen combustion does not generate carbon dioxide but only water vapors. Large-scale hydrogen production requires significant capital investments for separation and purification processes; thus, the cost of hydrogen markedly increases. Conventional technologies for hydrogen separation include solvent absorption, pressure swing adsorption (PSA), fractional/cryogenic distillation, and membrane separation. Membrane separation seems to be the most promising method because of its low energy consumption, continuous operation, low investment costs, and easy operation (Ockwig and Nenoff 2007).

Among all basic large-scale applications of polymer membranes, hydrogen recovery is the most important. In the 1970s, commercial success

of hydrogen-selective hollow-fiber membrane systems for the in-process recycling of hydrogen from ammonia purge gases has triggered large-scale application of the membrane gas separation. This technology has been extended to other situations for recovery of hydrogen from gas mixtures (H₂/CO or H₂/CH₄ ratio adjustment for syngas production) and has been successfully competing with cryogenic distillation and PSA processes. In the petrochemical industry, hydrogen recovery from refinery streams is an emerging field for membrane separation; it is a key approach to meet the increased demand of hydrogen (for hydrotreating, hydrocracking, or hydrodesulfurization processes) owing to new environmental regulations (Bernardo et al. 2009).

The main liability of hydrogen-selective membranes is that recompression of the permeated hydrogen is usually required. Therefore, an alternative method involves contaminate preferential permeation, and this method is treated as a new approach for hydrogen purification, primarily by using the carbon-based membranes. For example, hydrogen production by natural gas steam reforming yields a gaseous mixture containing hydrogen and also carbon dioxide and carbon monoxide. Solubility-controlled membranes (e.g., carbon-based membranes) are preferentially permeable for big-sized gas molecules (e.g., CO₂) in relation to hydrogen. This peculiarity offers evident economic advantages that maintaining/collecting hydrogen in the retentate at nearly bulk feed pressure mitigates the demands for costly hydrogen recompression steps, even though a CO₂ compression step is required (Ockwig and Nenoff 2007).

Hydrogen-separating membranes made of palladium alloys have been developed over the past 50 years into a technology that in some instances is used in practice. In an early work in the United States and in the former Soviet Union, relatively thick-walled tubes were used. This design has been advanced for ultra-purification of hydrogen and for its application in the semiconductor manufacturing processes and in the hydrogen generators for remote or small-scale usage. Current research topics in this area are concerned with membrane reactors for hydrogen gas supply for

fuel cells or for the chemical process industry. Palladium-alloy diffusers present a key component for the recovery of hydrogen radioisotopes which are used and produced by the nuclear fission in the fusion reactors. Hydrogen recovery from waste gases or purge streams (e.g., hydrotreater off-gas) presents a potentially large application of the palladium-based membrane technology. Coal gasification or natural gas reforming coupled to a palladium membrane reactor can offer an alternative huge source of hydrogen. Production of pure hydrogen for its use in fuel cells also seems to be another important mission of the palladium-based membrane reactor (Paglieri and Way 2002).

Hydrogen Selective Membranes

V. V. Volkov

A.V. Topchiev Institute of Petrochemical
Synthesis Russian Academy of Sciences
(TIPS RAS), Moscow, Russian Federation

As compared with other known fuels, hydrogen is abundantly available in the universe and possesses the highest energy content per weight unit. Moreover, in contrast to fossil fuels, the use of hydrogen as an energy source yields water as the only by-product. Hence, in recent years, the demand for hydrogen energy and production has been growing. Membrane separation process offers an attractive alternative to mature technologies such as pressure swing adsorption (PSA) and cryogenic distillation.

Hydrogen selective membranes are designed such that hydrogen concentration increases in the permeate. Based on the materials used, hydrogen selective membranes can be classified into four types: (i) polymer (organic), (ii) metallic, (iii) carbon, and (iv) ceramic. Metallic, carbon, and ceramic membranes are referred to as inorganic membranes. Depending on the type of the raw material, inorganic membranes can be classified into two groups: metal membranes and ceramic membranes. In addition, they could be divided into porous (microporous) and nonporous (dense) membranes (Adhikari and Fernando 2006). Microporous inorganic membranes include carbon and ceramic (amorphous or crystalline) membranes, and their separation characteristics are governed by the molecular sieving transport mechanism. Usually, dense inorganic membranes are based on a metal or on a polycrystalline ceramic. In these dense membranes, the fundamental operating mechanism involves the conduction of free electrons and the presence of specific catalytic surfaces in order to dissociate H_2 on the raw feed stream side and reassociate both protons and electrons on the product side. In such systems, hydrogen selectivity is typically very high because their dense structure prevents the transport of larger atoms and molecules (e.g., CO , CO_2 , O_2 , N_2 , etc.). This high selectivity provides the production of high-purity hydrogen (Ockwig and Nenoff 2007).

Historically, hydrogen separation is accomplished on the Pd-based membranes because they catalyze surface dissociation/reassociation processes and they are highly permeable to hydrogen. Palladium and Pd-alloy membranes can produce hydrogen gas on the ppb impurity levels. Since the late 1950s, small-scale Pd-based membrane modules have produced high-purity hydrogen at remote sites and for industrial, laboratory, or military purposes. There are various types of metallic membrane materials for hydrogen separation: (i) pure metals (Pd, V, Ta, Nb, and Ti); (ii) binary alloys of Pd such as Pd-Cu, Pd-Ag, Pd-Y, and also Pd-based alloys with Ni, Au, Ce, and Fe; (iii) complex alloys (Pd alloyed with three to five

other metals); (iv) amorphous alloys (typically Group IV and Group V metals); and (v) coated metals such as Pd on Ta, V, etc. (Adhikari and Fernando 2006). Dense ceramic membranes (e.g., perovskite, bismuth oxide, and solid electrolyte) have been developed and commercialized. Dense inorganic membranes are generally designed as a thin film on a porous inorganic support.

To overcome the relatively low permeance and high cost of dense metallic membranes, researchers are exploring the utility of high-permeance, less costly, and less selective microporous inorganic (silica or carbon or zeolite) membranes. The structure of these membranes presents a network of interconnected micropores with a diameter of ~ 0.5 nm. In general, microporous silicas show the highest hydrogen selectivities, and they exhibit the best H_2/N_2 selectivity which exceeds 10,000 for the membranes prepared by chemical vapor deposition (Ritter and Ebner 2007).

Since the 1970s, gas separation polymer membranes have been used industrially for hydrogen separation from gaseous mixtures in the United States (Ockwig and Nenoff 2007) and in the former Soviet Union (Yampolskii and Volkov 1991). Membranes made of glassy polymers (i.e., polymers with glass transition temperatures above the operating temperature) are used for removing hydrogen from gas mixtures. Examples of membrane materials for commercial polymer membranes include polyimide and polysulfone (asymmetric hollow fiber membranes) or polyvinyl trimethylsilane and cellulose acetate (asymmetric flat membranes). Such polymer membranes operate according to the solution-diffusion mechanism.

In general, hydrogen selectivity is low, moderate, and very high for polymeric, microporous inorganic, and metallic membranes, respectively. Polymeric membranes primarily operate at temperatures below 373 K, whereas carbon, silica, and dense ceramic membranes can function at higher temperatures (773–1,173 K). Metallic membranes can be used at ~ 573 –873 K.

Hydrogenation Contactors and Reactors

V. V. Volkov

A.V. Topchiev Institute of Petrochemical Synthesis Russian Academy of Sciences (TIPS RAS), Moscow, Russian Federation

Among all known catalysts for hydrogenation, metals of platinum family (Pt, Pd, Ni) are known to be most efficient and advantageous. Palladium catalysts for selective hydrogenation hold the unique position. Palladium and its alloys show an excellent potential to dissolve huge amounts of hydrogen, and as membrane materials, dense palladium and palladium alloy membranes are permeable only for hydrogen.

Pioneering studies by Gryaznov and his coworkers have encouraged the use of palladium and palladium alloy membranes in catalytic membrane reactors, including fundamental studies on selective hydrogenation of various unsaturated hydrocarbons, for example, acetylene, 1,3-pentadiene, and cyclopentadiene. The general concept can be formulated as follows: hydrogen is supplied to one side of the Pd-based catalytic membrane, and then it diffuses selectively through the membrane and approaches the other side of the membrane in its highly reactive form. Fundamental concepts on membrane catalysis and catalytic membrane reactors have been advanced in the 1960s, and the phenomenon of conjugating of chemical reactions with the evolution (dehydrogenation reaction)

Hydrogenation Contactors and Reactors, Fig. 1 Principle of a dense and self-supporting palladium alloy membrane (a thin-walled tube or a foil) for liquid phase hydrogenation. Hydrogen or hydrogen-containing source R-H₂ is supplied to the gas side; a to-be-hydrogenated substrate is supplied to the liquid side.

and consumption (hydrogenation reaction) of hydrogen on palladium membranes has been discovered in 1964 (Gryaznov et al. 2003). This concept is illustrated in Fig. 1.

Early studies in this direction have been focused on the use of relatively thick nonporous Pd or Pd-alloy membranes. Their thickness can be reduced by preparation of composite membranes on porous or nonporous supports. A critically new step providing reduced consumption of expensive noble metals is concerned with the development of catalytic membranes based on the metal-polymer composites. In this case, nonporous polymer matrix, for example, silicon rubber, is loaded with palladium nanoparticles (Gryaznov et al. 2003).

Pd-based catalytic nanoparticles can be immobilized on the surface of porous inorganic or polymeric membranes, thus providing a new type of catalytic membrane reactor, called catalytic contactor. According to the proposed classification (Miachon and Dalmon 2004), depending on the mode of supply of reagents, two types of catalytic contactors exist: an interfacial contactor and a flow-through contactor. In this case, a key point is concerned with localization of reactants in the very volume where the catalyst is deposited.

The typical example of hydrogenation on an interfacial catalytic contactor is related to removal

Dehydrogenation of R-H₂ occurs on the gas-side surface and this process is endothermic; both reactions are accompanied by hydrogen transfer. Due to excellent thermal conductivity of the membrane, the heat released by hydrogenation can be utilized to facilitate endothermic dehydrogenation (autothermic operation) (Dittmeyer et al. 2004)

of dissolved oxygen (DO) from water (Volkov et al. 2011). Hydrogen and DO-containing water are supplied to the opposite sides of a hydrophobic porous catalytic membrane. In this case, membrane material should be non-wettable for water (hydrophobic) in order to provide liquid-free pores and high-rate hydrogen transmembrane mass transfer. The Pd catalyst is placed onto the water-contacting membrane surface. Water deoxygenation by catalytic membranes, including palladium-loaded hollow fibers, is accomplished by the chemical reaction between dissolved oxygen and hydrogen in the presence of the palladium catalyst.

In a flow-through contactor, reactants are forced to flow through a porous catalytic membrane, i.e., through the Pd-loaded pores. This enables to control and rule residence time of reacting species in the active zone of the catalytic membrane.

Hydrophilic Membrane

Fu Liu

Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

The hydrophilic term characterizes a membrane in relation to its behavior in an aqueous environment. The membrane's interaction with water is determined by its chemical composition and corresponding surface. Hydrophilic membranes have an affinity to water. Their surface chemistry allows these materials to be wetted immediately. Hydrophilic membrane is extremely imperative in water treatment to avoid the fouling of organic matter on the membrane surface. Diverse methods have been developed to render the hydrophobic polymeric membranes with improved hydrophilicity including surface modification and blending modification.

Hydrophilic Modification

Fu Liu

Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

The developments and applications of PVDF, PSf, or other polymeric membranes are limited in the areas of purification and separation of aqueous

solution systems such as drinking water production, wastewater treatment, and bio-separation due to its hydrophobic nature. The critical problems of PVDF membrane lie in:

1. The surface energy of PVDF, which is very low, and the critical surface tension (γ_c) of PVDF, $-\text{CF}_2-$, and $-\text{CH}_2-$, which is 25 mN/m, 18 mN/m, and $\gamma_c = 31$ mN/m, respectively. This results in the poor wettability of the PVDF membrane. Therefore, the pure water flux is usually low due to the strong hydrophobic nature of PVDF.
2. The hydrophobic PVDF membrane is susceptible to fouling while treating aqueous solution containing natural organic matters, e.g., proteins. Proteins are prone to be easily absorbed onto the membrane surface or block the surface pores, decreasing the permeability and the final separation performance, depressing the lifetime of the membranes and subsequently causing more operation costs of the replacement and maintenance of the membrane modules.

One major possible reason for the protein fouling on the hydrophobic PVDF membrane is that there are almost no hydrogen bonding interactions in the boundary layer between the PVDF membrane interface and water. The repulsion of water molecules away from hydrophobic PVDF membrane surface is a spontaneous process with an increasing entropy, and therefore, protein molecules have a tendency to adsorb onto membrane surface and dominate the boundary layer. In contrast, the membrane with the hydrophilic layer possesses a high surface tension and is able to form the hydrogen bonds with surrounding water molecules to reconstruct a thin water boundary between the membrane and bulk solutions. It is difficult for hydrophobic solutes, like some proteins, to approach the water boundary and break the orderly structure because an increase of energy would be required to remove the water boundary and expose the PVDF membrane surface.

Therefore, hydrophilic modification is necessary to improve the hydrophilicity of PVDF membranes through versatile methods to enhance the lifetime and reduce the operation cost of PVDF

membranes. Different modification ways have been explored to tailor the surface engineering of the PVDF membrane in recent years. Two straightforward ways are usually used to catalogue the diverse hydrophilic and fouling resistant modification techniques, which can be mainly classified into surface modification and blending modification. Surface modification is usually achieved by coating or grafting a functional layer on the prepared membrane surface, in which most of the modified sites occurred on the top and/or bottom surface of the membrane, excluding the pores inside the membrane, due to the limited diffusion ability of the modifying agents into the membrane pores. Blending modification is usually used to achieve the desired functional properties along with the membrane preparation; therefore, the preparation and modification process can be accomplished in a single step. Both surfaces and inside pores of the membrane have a window of opportunity to be modified synchronously through the synergy effect between PVDF and compatible additives (Fu Liu 2011).

Hydrophilic-Hydrophobic Membrane

► Amphiphilic Membrane

Hydrophilicity

Fu Liu
Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

Hydrophilicity refers to a membrane with hydrophilic property. Hydrophilicity is the tendency of a

surface to become wet or to absorb water. Generally speaking, when a surface shows hydrophilicity, the molecules of water form bonds with the molecules of the surface.

In most cases, hydrophilicity refers to how readily a surface reacts with water molecules. It is also possible to measure the hydrophilicity of a surface when it comes into contact with other liquids. Understanding how hydrophilic a surface can help engineers to develop materials that show the proper amount of hydrophilicity for their intended use.

There are ways of determining hydrophilicity via utilizing precise mathematical formulas. If droplets of water remain formed on the surface and roll off easily when the surface is angled toward the ground, the material is said to be particularly hydrophobic. If, on the other hand, water is absorbed into the surface and that surface becomes wet, it is hydrophilic. The water contact angle of a hydrophilic membrane is usually below 90°.

Hydrophobic Membranes

Fu Liu
Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

The hydrophobic term characterizes a membrane in relation to its behavior in an aqueous environment. The membrane's interaction with water is determined by its chemical composition and corresponding surface. Hydrophobic membranes have little or no tendency to absorb water, so that a droplet remains on the surface. The water contact angle of a hydrophobic membrane is usually over 90°.

Most polymeric membranes can be regarded as hydrophobic membranes, e.g., PVDF, PTFE, PP, PE, and PSf membranes. Hydrophobic membranes usually possess an unique advantage in membrane distillation, oil/water separation or membrane contactor.

Hydrophobic-Hydrophilic Interaction

Fu Liu

Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

The hydrophobic effect is the observed tendency of nonpolar substances to aggregate in aqueous solution and exclude water molecules (IUPAC 1997; [Interfaces and the Driving Force](#) 2005). The name, literally meaning “water fearing,” describes the segregation and apparent repulsion between water and nonpolar substances. The hydrophobic effect explains the separation of a mixture of oil and water into its two components and the beading of water on nonpolar surfaces such as waxy leaves. At the molecular level, the hydrophobic effect is important in driving protein folding ([The Binding of Benzoarylsulfonamide](#) 2003), formation of lipid bilayers and micelles, insertion of membrane proteins into the nonpolar lipid environment, and protein-small molecule interactions. The hydrophobic surface is usually defined as the water drop contact angle is over 90°.

Hydrophilicity is the tendency of a surface to become wet or to absorb water. Generally speaking, when a surface shows hydrophilicity, the molecules of water form bonds with the molecules of the surface via highly dynamic hydrogen bonds. The hydrophilic surface is usually defined as the water drop contact angle is below 90°.

Hydrophobicity

Wolfgang M. Sigmund and Shu-Hau Hsu

Department of Materials Science and Engineering, University of Florida, Gainesville, FL, USA

Department of Energy Engineering, Hanyang University, Seoul, Republic of Korea

Hydrophobicity is the term frequently used in surface chemistry describing the tendency of moving away from water or aqueous environment. The name, the combination of *hydro-* and *phobos*, simply stands for *water* and *fear* in Attic Greek. A hydrophobic surface tends not to be dissolved or wetted by water. Water forms distinct droplets on a hydrophobic surface, and their contact angles increase as its hydrophobicity increases. For more details, please refer to the section of Young’s Model.

Hydroprocessor Purge Gases

Arnaud Baudot

Physics and Analysis Division, IFP Energies nouvelles, Solaize, France

The demand for hydrogen is constantly increasing in refineries due to more and more stringent sulfur content specifications for fuels (leading to an increasing hydrogen consumption in hydrodesulfurization processes) and a growing heavy crude consumption, which results in a higher worldwide demand for highly hydrogen-consuming upgrading processes, such as hydrocracking. In this changing landscape, permeation membranes constitute an elegant option for the recovery of hydrogen that is nowadays wasted in an array of refinery off-gases, such as fuel gas, PSA tail gas, FCC gas, catalytic reformer off-gases, or hydrocracker/hydrotreater off-gases.

Nowadays, three main membrane providers offer hydrogen purification permeators:

- *Air Products* with the *Prism*[®] silicon-coated polysulfone membranes (issued from *Monsanto*). *Air Products* claims that the life-time of the *Prism*[®] modules can be more than 15 years.
- *Ube Industries* with polyimide hollow fiber membranes.
- *Air Liquide* with the *MEDAL* polyimide and high selectivity polyaramide membranes.

All those membranes are based on glassy polymers and offer a diffusion-based hydrogen selectivity. Today's membranes have high H₂/CH₄ selectivities (from 35 to 200 at 80 °C (Roman et al. 2001)). For instance, *Air Products* claims that a single-stage array of *Prism*[®] modules is able to raise the concentration of gases from 10–30 % up to 70–90 % (*Air Products website*), while *MEDAL* membranes are able to raise the concentration of a gas at 51 bar from 86 % in hydrogen up to 98 % with a permeate pressure at 30 bar and a residue containing 52 % of hydrogen at 50 bar (*Medal website*).

In 2003, it was reported that more than 400 hydrogen permeators were installed worldwide (Monereau 2003) while approximately 100 were operated in refineries (Baker 2002). As there are more than 500 refineries in the world, it is clear that the potential market for this type of membrane applications is far from saturated. Nevertheless, three main limits still hinder the wide acceptance of permeation-based hydrogen purification in the refining industry:

- The purified hydrogen is recovered at low pressure in the permeate side and requires compression in order to feed it back to reactors. As such, PSA (pressure swing adsorption) is a more attractive process, as the produced purified hydrogen is delivered directly at high pressure.
- The sensitivity of membrane to contaminants, such as water vapor, higher hydrocarbons, or acid gases. The installation of permeators generally requires at first a very detailed analysis of the contaminants present in the feed, even at traces level, in order to design pretreatment operations. A wide array of solutions can be

Hydroprocessor Purge Gases, Table 1 Ube Industries membrane material compatibility against contaminants (*Ube Industries website*)

Contaminants	Maximum allowable content
Water vapor	Up to saturation
H ₂ S	3 % vol
NH ₃ and amines	100 ppm vol
Methanol	5 % vol
Methyl ether	5 % vol
Benzene	1 % vol
Toluene	2000 ppm vol
C ₅ + hydrocarbons	Up to saturation

used in order to remove poisonous compounds: coalescing filters in order to remove aerosols, sorbent beds, or even complete PSA (pressure swing adsorption) or TSA (temperature swing adsorption) units (Monereau 2003). This can lead to a significant increase of investment and operating costs. It should be reminded here that recent hydrogen purification membranes are still relatively tolerant to contaminants (Table 1). This is particularly true if membrane modules are operated at higher temperatures (from 80 °C to 110 °C), which results in lowering of the sorption of contaminants.

- The membrane's mechanical integrity can be damaged in transient operating conditions, especially in the case of an emergency blow-down of the membrane-based process. In certain cases, the membrane module can be submitted to pressures differences larger than its mechanical tolerance. Solution is nowadays proposed by membrane providers in order to monitor automatically the pressure balance between the feed and the permeate compartment when operating condition limits are reached (Monereau 2003).

Hydrothermal Stability of Zeolite

Reyes Mallada

Department of Chemical and Environmental Engineering and Aragon Nanoscience Institute, Universidad de Zaragoza, Zaragoza, Spain

Zeolites are microporous crystalline aluminosilicates, and its Si to Al ratio and ion exchange determines its main properties. The most important application of zeolites is catalysis, and in particular zeolite Y and ZSM-5 are the catalysts in the fluid catalytic cracking (FCC) process for gasoline production in refineries. The acidity of the zeolites, related to its aluminum content and the shape selectivity given by the microporous network of cavities, are the main properties that contribute to the success of the zeolites in the cracking reactions. The production of coke in the FCC implies a continuous regeneration step at temperatures up to 800 °C in the presence of steam. Under these severe hydrothermal conditions, the activity and stability of zeolite is affected mainly due to the dealumination of the zeolite. The preparation of USY, ultrastable zeolite Y, consists of increasing the Si/Al ratio of the zeolite, decreasing the activity but increasing hydrothermal stability. Similarly the addition of phosphorous also stabilizes the aluminum framework in the zeolite (Martinez 2008). Finally the creation of the mesopores in the zeolites for FCC is also desired to crack larger molecules. The introduction of mesopores is accomplished by alkali treatment, but the thermal and hydrothermal stability again decreases, since the desilication effect of the NaOH solution, and this made some Al sites in the interior crystal become the Al sites

at the edge of the crystal, which would be extracted easily by calcination and steaming treatments. In general it could be concluded that there is a trade-off in the aluminum content of the zeolite, as it increases acidity and catalytic activity; however, hydrothermal stability decreases.

Similarly some problems related to hydrothermal stability of zeolite A, Si/Al = 1 in dehydration of organic solvent by pervaporation, has been reported. The damage effects of water on LTA zeolite membranes were verified and occur at water concentrations higher than 15 % and temperatures of 70 °C. The effects of water content in the feed and PV temperature on the membrane stability were recently investigated Li et al. (2007). The preliminary results show that the damage of LTA zeolite membrane by water mainly occurs in the grain boundary regions. The amorphous-like structure of the grain boundary is probably the principal reason for the low hydrothermal stability of LTA zeolite membrane at high water concentration, as the case of mesoporous molecular sieving materials. Solutions to this problem include the use of a zeolite with a higher Si/Al ratio, such as CHA membrane (Sato et al. 2012), and posttreatments in zeolite LTA such as silylation.

Hydrothermal Synthesis

- [Perovskite Powder Preparation Methods](#)

Hydrothermal Synthesis of Zeolite

Reyes Mallada

Department of Chemical and Environmental Engineering and Aragon Nanoscience Institute, Universidad de Zaragoza, Zaragoza, Spain

Zeolites are crystalline, hydrated aluminosilicates having microporous, regular structures that occur naturally. The synthetic zeolites early developed by Barrer and Milton in the late 1940s (Cundy and Cox 2005) were prepared using a hydrothermal treatment at high temperature and pressure mimicking the conditions for the synthesis of these minerals in nature. There are more than 200 framework types, recognized by the International Zeolite Association (IZA, <http://www.iza-structure.org>), but only a few have been synthesized as

membranes being the most important: MFI, LTA, FAU, CHA, and MOR.

A hydrothermal treatment implies the use of an aqueous solution, synthesis gel, which is heated in an autoclave at a certain temperature under autogenous pressure. The chemicals in the synthesis gel include the silicon and aluminum sources in the presence of a mineralizing agent commonly sodium hydroxide or alternatively fluoride ion and in some cases a structure-directing agent (SDA) that facilitates the synthesis of the desired zeolite structure.

In a conventional hydrothermal synthesis all the reactants are mixed together and dissolved in the highly alkaline synthesis gel and heated up in the autoclave up to the selected temperature. After an induction period crystalline zeolite nuclei could be detected later, the nuclei start growing and finally all the amorphous material is converted into zeolite. There are several

Hydrothermal Synthesis of Zeolite, Fig. 1 Steps in Hydrothermal Synthesis of Zeolites

mechanisms proposed for the hydrothermal synthesis of zeolites (Cundy and Cox 2005), but in general they comprised the dissolution of the ionic species, organization of the aluminum and silicon tetraedra species around the structure-directing agents forming initial primary building units, that result in secondary building units, that finally form the polyhedra that comprise the zeolite structure, see Fig. 1.

The most probable mechanistic pathways in zeolite formation are described in sequence: induction period, nucleation, and crystal growth. The nucleation and crystal growth could be separated, giving rise to the ► [seeded hydrothermal synthesis method of zeolite membranes](#).

The composition of the synthesis gel influences the crystallization and the zeolite formed. Firstly the *Si/Al ratio* will define the ion exchange capacity, as one atom of Si is replaced by Al a charge defect is created. Also the hydrophobicity of the zeolite increases as the Al content increases, being zeolite A with a $Si/Al = 1$ the most hydrophilic and silicalite with $Si/Al = \infty$ the most hydrophobic. *The solvent*, as water (and sometimes alcohols) has a direct effect on the concentration of reactants, and therefore on the nucleation and growth rates. Alcohols are often added to retard the hydrolysis of the silicon alkoxide which allows controlling the crystal size by reducing the polymerization rate of the silica. The amount and nature of the solvent will also affect the viscosity of the synthesis gel, and therefore the diffusion rates of reactants during synthesis. The presence of *the structure-directing agent (SDA)*, facilitates zeolite synthesis, but in zeolite layers, and especially in membranes, may cause complications associated to template removal. *The mineralizing agents* – they also have a direct effect on the synthesis dynamics and in the hydrophilic/hydrophobic character of the resulting membranes.

The synthesis time of zeolites could vary from several hours to days in conventional ovens at temperatures ranging from 90 °C to 200 °C. It is important to mention that in the last decade the *microwave hydrothermal assisted method* (see ► [Microwave synthesis of zeolite membranes](#)) has contributed to shorten considerably synthesis

time of zeolites and zeolite membranes (Li and Yang 2008) due to a more efficient volumetric heating compared to conventional heating.

Hydroxylation of Benzene to Phenol by Membrane Contactors

Teresa Poerio

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The search for new routes for phenol production based on the one-step direct benzene oxidation became more intensive because this reaction is a little selective, being the phenol more reactive than benzene, and over-oxygenated by-products occur (Molinari and Poerio 2009). To slow down consecutive catalytic reactions, a membrane contactor has been employed. This system permits to combine membrane separation and catalytic reaction in one unit operation. The separation of a product from the reaction mixture is one of the advantages in using a membrane in a reactor and permits to obtain improvements in terms of yield and selectivity in equilibrium-limited reactions and in consecutive catalytic reactions (Armor 1998).

The benzene hydroxylation to phenol was carried out in a biphasic membrane contactor (Fig. 1) in which a flat-sheet membrane separates two

Hydroxylation of Benzene to Phenol by Membrane Contactors, Fig. 1 Scheme of the membrane contactor

compartments containing two immiscible phases: an acidic aqueous phase (containing an iron catalyst and hydrogen peroxide as the oxidant) and an organic phase (only benzene).

The benzene phase, in the double task of stripping solution and reagent, avoided the use of other organic solvents with benefit in product recovery. In this system the benzene permeates across the membrane from the organic phase to aqueous membrane interface where the interfacial oxidation reaction takes place. Then the formed phenol permeates back across the membrane to the organic phase where it takes shelter from over-oxidation reaction. The high value of phenol selectivity (98 %) in the organic phase and interesting phenol productivity ($3.60 \text{ g}_{\text{ph}}\text{g}_{\text{cat}}^{-1} \text{ h}^{-1}$) were obtained, thanks to its extraction in the organic phase, avoiding further contact between phenol and the catalyst, which was soluble in the aqueous phase (Molinari et al. 2006). The drawback of this system was the low rate of phenol extraction in the organic phase. Indeed, phenol that does not cross rapidly to the membrane reacts further to generate over-oxidation products such as benzoquinone, biphenyl as trace, and tars. In order to avoid/reduce tar formation and promote phenol extraction in the organic phase, different strategies have been applied (Molinari and Poerio 2011). For example, the use of dissolved salts such as sodium sulfate in the aqueous reacting phase increased phenol extraction in the organic phase but also increased reaction kinetics, thus promoting black solid (tar) formation and

reducing the phenol productivity (0.64 gh^{-1}). The use of different operating pH values and different organic acids delayed and in some tests avoided tar formation but also gave a reduction of the phenol selectivity and then productivity. Different catalysts, such as vanadium-based vanadyl (IV) acetylacetonate (VAAC) and vanadium(III) chloride (VC), were also tested, and the obtained results evidenced improved productivity (0.97 vs $0.78 \text{ g}_{\text{ph}}\text{g}_{\text{cat}}^{-1} \text{ h}^{-1}$) using VC compared to VAA-C. No tars formation has been observed, but the system productivity was significantly lower than that obtained using an iron(II) catalyst (Molinari et al. 2012).

A direct synthesis of phenol from benzene was also studied using a photocatalytic membrane contactor (PMC), using TiO_2 as suspended catalyst (Molinari et al. 2009).

The PMC allowed to obtain the phenol production and its separation, although the formation of intermediate oxidation by-products, like benzoquinone, hydroquinone, and other oxidized molecules, was observed. Nevertheless, the acidic condition allowed to control the selectivity toward the intermediates, permitting to obtain a lower formation and extraction of the over-oxidized products.

Hydroxypropyl Cellulose (HPC) Membrane

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu
Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Hydroxypropyl cellulose (HPC) is a water-soluble polymer, often used as a thickening agent, a tablet binder, and a film-coating material for drug release. Combining with ethyl cellulose (EC) or cross-linked with polyacrylic acid, HPC can be used as a mucoadhesive delivery system or oral delivery system, where the drug release rate and the drug dosage can be controlled (Kamel

et al. 2008). Figure 1 shows the synthetic route for making hydroxypropyl cellulose. The hydroxyl groups on the glucose unit of cellulose can be partially or completely substituted by hydroxypropyl groups through an etherification reaction. The maximum molar substitution is 3, and consequently, the viscosity of the polymer increases with the degree of polymerization. The broad range of accessible viscosity leads to different applications in pharmaceutical formulation, e.g., hydroxypropyl cellulose with low viscosity has been used as tablet binder, while those with medium and high viscosities have been used in the formulation of sustained-release matrices, especially in oral pharmaceutical products (Guo et al. 1998).

Due to the excellent water solubility, hydroxypropyl cellulose can be mixed with other water-soluble polymers, such as chitosan, to fabricate pervaporation membranes after cross-linking. The composite membrane has been employed to dehydrate isopropanol, with excellent flux and selectivity improvement, when compared with pure chitosan membranes (Veerapur et al. 2007).

Biocompatible hydroxypropyl cellulose has been used as a backbone in gene delivery vectors via grafting modifications, where the comb-shape copolymer exhibits low cytotoxicity and high transfection capability in a gene delivery process (Xu et al. 2009). Similarly, membranes composed of a mixture of hydroxypropyl cellulose and ethyl cellulose can offer special release profiles in drug delivery application (Sakellariou and Rowe 1995).

Hyflon® AD

Marco Avataneo

RD&T, Solvay Specialty Polymers, Bollate (MI), Italy

Hyflon® AD is a family of amorphous perfluorinated copolymers of tetrafluoroethylene (TFE) and 2,2,4-trifluoro-5-trifluoromethoxy-1,3-

Hyflon® AD, Fig. 1 Hyflon® AD chemical structure

Fig. 2 Density, glass transition, and refractive index for the two commercial grades of Hyflon® AD

Property		AD 40	AD 60
Density	g/cm ³	1.98	1.93
T _g	°C	95	125
Refractive index		1.331	1.327

dioxole (TTD) (Colaïanna et al. 1999). The chemical structure of these completely fluorinated (i.e., *perfluoro*-) copolymers is shown in Fig. 1.

Hyflon® AD and the monomers (Navarrini et al. 1999) used for its polymerization are manufactured by Solvay.

The presence of TTD units in the copolymer prevents the formation of crystalline phases (Milani et al. 2008) and completely amorphous materials are obtained when its content is higher than approximately 20 % (Arcella et al. 2003). The glass transition temperature (T_g) of Hyflon® AD copolymers increases with the content of the cyclic monomer up to 192 °C which corresponds to value of the TTD homopolymer.

The commercial grades of this amorphous perfluoropolymer are Hyflon AD® 40 and Hyflon® AD60, whose density, T_g, and refractive index are shown in Fig. 2. The numbers close to the Hyflon AD trade name indicates the molar content of TTD which is then equal to 40 % for AD40 and 60 % for AD60.

Hyflon AD® 40 is available both as high molecular weight and a low molecular weight grade, whereas Hyflon AD® 60 is produced only in one grade.

All Hyflon® AD copolymers display high solubility in fluorinated solvents and, in particular, in perfluorinated solvents like Galden® perfluoropolyethers (from Solvay) and Fluorinert® FC40 perfluorotributylamine (from 3M). This property, combined with low solution viscosity (Arcella et al. 1999), makes Hyflon® AD an ideal material for solution process technologies: uniform and thin films or coatings, down to submicron thicknesses, can be easily obtained by casting or coating techniques followed by solvent evaporations at temperatures well below the typical baking temperatures of semicrystalline perfluoropolymers.

Hyflon[®] AD copolymers combine excellent optical properties (high optical transparency, low refractive index) and a low dielectric constant with outstanding chemical and temperature resistance. They are therefore choice materials for active or protective thin layers into electronics, such as displays, wafer handling equipment, and other applications where very high optical transparency, surface contamination repellency, or static protection is required.

High transparency and high purity are the main criteria for pellicles and for electronics applications. To satisfy these demanding specifications, ultrapure grades of this material are manufactured by submitting Hyflon[®] AD to a photochemical fluorination process (Tortelli and Calini 2002) in order to completely eliminate the functional polymer end groups and any other residual contaminants that can be derived from the polymerization process.

Gas separation membranes based on Hyflon[®] AD are also of increasing interest in industrial applications (Merkel et al. 2006; Bernardo et al. 2009) due to a remarkable combination of high chemical resistance, low hydrocarbon-vapor sorption, and high resistance toward swelling and plasticization. The diffusivity of a gas through an amorphous perfluoropolymer is well described by its fractional free volumes (FFV), a common measure of the free space available, in a polymer matrix, for molecular transport, which is directly correlated to the T_g of the material. On the contrary, the higher the permeability the lower the selectivity is. Hyflon[®] AD60 having a T_g (125 °C) is a good compromise between moderately high selectivity and good permeability. Typical applications are O₂/N₂ enrichment, He/H₂ separation in space industry, and purification of natural gas.

Hyflon[®] AD Membranes

Marco Avataneo

RD&T, Solvay Specialty Polymers, Bollate (MI), Italy

Hyflon[®] AD membranes are made of amorphous perfluorinated copolymers produced by Solvay and composed by tetrafluoroethylene and 2,2,4-trifluoro-5-trifluoromethoxy-1,3-dioxole units (Colaïanna et al. 1999). Hyflon[®] AD40 *high-low molecular weight*, Hyflon[®] AD40 *high molecular weight* and Hyflon[®] AD60 are three commercial grades of this family. All of them are suitable for the preparation of membranes. Even if Hyflon[®]

AD can be melt processed by molding or extrusion, the solution-based technologies are the preferred methods as they allow the preparation of thinner and more uniform membranes: spin-coating deposition and casting are used to obtain ultrathin, uniform thickness coating on flat surfaces, whereas nonplanar surfaces are more preferably coated by dipping.

By selecting the proper coating procedures, dense symmetric, asymmetric, or composite membranes can be obtained (Gordano et al. 1999; Arcella et al. 2003, 2009, 2010). Dense membranes are prepared by deposition of a thin film of the fluoropolymer solution followed by solvent evaporation, whereas asymmetric membranes are obtained by phase inversion technique: after deposition, the support coated by the fluoropolymer solution is dipped into a coagulation bath containing a non-solvent, for example, n-pentane. Composite membranes, made of a layer of the perfluorinated polymer on a porous support, like polyethersulfones and polyvinylidene fluoride (Gugliuzza and Drioli 2007; Gordano et al. 2001; Gugliuzza et al. 2006), can be prepared by coating the solution on a porous flat surface or hollow fiber (Jansen et al. 2006), followed by solvent evaporation.

Hyflon[®] AD solutions are prepared, even at concentration higher than 10 %, by dissolving the fluoropolymer powder at room temperature (or above) in Galden[®] perfluoropolyethers. These latter are a family of fluorosolvents manufactured by Solvay in several grades and characterized by different boiling points: those preferred for the preparation of membranes have a boiling point between 55 °C and 170 °C. Alternative solvents are perfluorocarbons, perfluorotriethylamine, and hydrofluoroethers.

The combination of excellent solubility and low solution viscosity, in particular for the grades AD40 *low molecular weight* and AD60, greatly simplify the purification of the fluoropolymer solutions by filtration (Arcella et al. 1999). In fact, to ensure the preparation of membranes with no defects, it is essential to avoid the presence of both suspended and dissolved contaminants.

Hyflon[®] AD membranes shows not only an extremely hydrophobic character (contact angle vs. water 120°) but also an oleophobic character, being the contact angle vs hexadecane ca. 60°, a value which implies fouling resistance.

Separation membranes based on Hyflon[®] AD are of increasing interest in industrial applications due to a remarkable combination of high chemical resistance, low hydrocarbon vapor sorption, and high resistance toward swelling and plasticization. The permeability of a gas through an amorphous perfluoropolymer is linearly correlated to its glass transition (T_g) (Arcella et al. 1999), and therefore, the higher the T_g, the higher the permeability, assuming a constant solubility coefficient. High T_g amorphous perfluoropolymers, like Teflon[®] AF (160 °C and 240 °C, two grades), offer high permeability to gases but also low selectivity. On the contrary, Hyflon[®] AD40 (T_g = 95°) and Cytop[®] (T_g = 108 °C) show lower permeability but higher selectivity. Among all the commercial amorphous perfluoropolymers, Hyflon[®] AD60, which has an intermediate T_g (125 °C), represents the best compromise between selectivity and permeability.

Gas permeability data for symmetric dense membranes of Hyflon[®] AD40 and Hyflon[®] AD60 at 35 °C and 50 psig are reported in Table 1. As previously indicated, Hyflon[®] AD 60 shows permeability higher than that of Hyflon[®] AD40. As diffusivity is attributed to the presence of voids at the molecular scale, the permeability tends to diminish with the increase of the volume of the gas molecule. Carbon dioxide, due to its paramount solubility in fluoromaterials (Kirby and McHugh 1999; McHugh et al. 1996), does not follow this rule being its permeability higher than that expected on the basis of its critical volume.

The combination of high permeability with good selectivity and with high chemical and swelling resistance makes these materials particularly useful for several applications such as gas separation, membrane contractors, membrane distillation, and pervaporation processes (Sanders et al. 2013; Bernardo et al. 2009; Gordano et al. 2001; Gugliuzza et al. 2006). Typical applications are purification of natural gas, O₂/N₂

Hyperbranched Polyimide Membranes, Preparation and Characterization of

Petr Sysel

Department of Polymers, Institute of Chemical Technology, Prague, Czech Republic

Due to their structure, the macromolecular compounds can be classified as linear, branched, and

cross-linked polymers. The dendritic topology (dendrimers, hyperbranched polymers) has recently been recognized as a new class of macromolecular architecture (Tomalia 2005). Hyperbranched polymers are highly branched macromolecules. The highly branched structure and a large number of terminal functional groups are their important structural features. Hyperbranched polymers often can be simply prepared by a direct one-step polymerization of multifunctional monomers using a single-monomer (AB_x, most frequently AB₂ monomer) or double-monomer (A₂+B₃) methodology. (A and B represent two kinds of functional groups

which can react with each other but cannot undergo self-reaction.) Many kinds of hyperbranched polymers, e.g., polyesters, poly(ether ketone)s and polyamides, have been investigated as novel dendritic macromolecules so far (Gao and Yan 2004). An increasing attention has been also devoted to hyperbranched polyimides due to a potentially possible connection of the known advantages of linear or cross-linked polyimides with those of hyperbranched polymers (Jikei and Kakimoto 2004).

Polyimides exhibit very good chemical, mechanical, and dielectric stability at temperatures from $-150\text{ }^{\circ}\text{C}$ to $250\text{ }^{\circ}\text{C}$. These rigid

Hyperbranched Polyimide Membranes, Preparation and Characterization of,

Fig. 1 Preparation of hyperbranched polyimide based on 4,4'-oxydiphthalic anhydride and 4,4',4''-triaminotriphenylmethane (via a polyimide precursor (polyamic acid))

polymers with a high glass transition temperature are mostly used in (micro)electronics, aircraft industry, and as polymeric separation membranes. Linear polyimides are traditionally prepared by two-step polymerization. The polyimide precursor, polyamic acid (the most often a solution in 1-methyl-2-pyrrolidone), is prepared from an aromatic dianhydride and aromatic diamine. This precursor is transformed into a polyimide using thermal or chemical imidization (Hergenrother 2003). It is difficult to prepare hyperbranched polyimides from AB_x monomers due to the high reactivities of A and B groups. Therefore, they are often prepared by the combination of bifunctional (A₂) and trifunctional (B₃) monomers. The ratio of anhydride and amine component determines the kind and the ratio of end groups. Nevertheless, their synthesis from trifunctional monomers often a rather complex structure requires special and controlled reaction conditions to avoid gel formation. As such triamines were used, e.g., tris(4-aminophenyl)amine or 1,3,5-tris(4-aminophenoxy)benzene (Jikei and Kakimoto (2004)).

Recently, hyperbranched polyimides were auspiciously tested as polymeric membranes for gas separation. Gas transport properties of the membranes made of 1,3,5-tris(4-aminophenoxy)benzene and 4,4'-(hexafluoroisopropylidene) diphthalic anhydride were monitored and these properties were compared with those for linear polyimides with a similar chemical composition. The permeability, diffusivity, and solubility of the gases were higher in the membranes based on hyperbranched polyimides (Suzuki et al. 2004). Similarly, the permeability coefficients of hydrogen, carbon dioxide, oxygen, nitrogen, and methane in the membrane from the hyperbranched polyimide based on commercially available 4,4',4''-triaminotriphenylmethane and 4,4'-oxydiphthalic anhydride (Fig. 1) were 2–3.5 times higher than those in the membrane from linear polyimide based on 4,4'-diaminodiphenylmethane at comparable selectivities (e.g., oxygen/nitrogen about 6) (Minko et al. 2012). It seems that the favorable effect of both the chain character (rigidity, interactions, arrangements, higher-free volume) and selective gas sorption (cavities, end-capping groups) contributes to this increase.

Hyperbranched Polyimides

Ryohei Shindo, Shinji Kanehashi and
Kazukiyo Nagai
Department of Applied Chemistry, Meiji
University, Tama-ku, Kawasaki, Japan

Hyperbranched polyimides are formed by repeated division of branches of comb polyimides. Hyperbranched polymers are synthesized by polymerization of AB₂-type monomers and consist of branched structures and mixed straight chains (Fig. 1). Rigorous structural analysis cannot be performed because branching does not regularly occur. However, hyperbranched polymers show properties differing from a normal linear polymer because entanglement of the intermolecular chains is difficult. Flory (1952) showed that gelation of polymerization of AB_x-type monomer cannot be statistically performed. Kricheldorf et al. (1982) reported the use of AB₂-type monomer as one component in copolymers, but their results lacked research attention. Hyperbranched polymers containing various

Hyperbranched Polyimides,

Fig. 1 Architecture of polymers

H

repeating units have been reported since the synthesis of hyperbranched polyphenylene by one-step polymerization of AB_2 -type monomer was reported as a simple synthesis method of polymers, which were similar in structure to dendrimers by Kim and Webster (1990) of Du Pont. However, dendrimers as structurally-controlled polymers have been actively studied in the field of medicine and for use in catalytic reaction and photoreaction. Hyperbranched polymers have an obvious advantage in synthesis compared with dendrimers. Thus, these polymers can be used as an alternative to dendrimers and a low-viscosity polymer in a wide range of areas. Polyimide is a condensation polymer synthesized from dicarboxylic anhydride and primary diamine. Aromatic heterocyclic polyimides show good mechanical property and superior thermal and oxidation stability. These polyimides are widely used in place of metal and glass. They are also used for high-functional application in electrical engineering, electronic engineering, automobiles, aircraft, and packaging industry. Linear aromatic polyimides are known as polymers, which have poor workability because they are insoluble and infusible in the rigidity of the main chain structure. However, solubility for organic solvent can remarkably improve by the introduction of a multiple branching structure. Hyperbranched polyimides with

4-methylphthalimide as end groups show low dielectric constant, birefringence, and high optical transparency. These qualities result from the improvement in isotropy of molecular chains by the introduction of a multiple branching structure and inhibition of the formation of charge-transfer complex, causing coloration on linear polyimides. For aromatic amine to react easily with acid anhydride at room temperature, isolation of AB_x -type monomer with these functional groups in a molecule is difficult because of their instability. Poly(amic acid ester) is synthesized by AB_2 -type monomer, which has a carboxylic acid ester and two amino groups in a molecule and a condensation agent. Hyperbranched polyimides are synthesized by chemical imidization of poly(amic acid ester) (Yamanaka et al. 2000). Hyperbranched polyimides can be synthesized by self-polycondensation of AB_x -type monomers with imide ring in the monomer framework. Thompson et al. (1999) reported that hyperbranched polyetherimides are synthesized by thermal polycondensation of AB_2 -type monomers with fluorine (A functional group) and silylated phenolic hydroxyl group (B functional group), which can be detached in a molecule. When A_2 - and B_3 -type monomers are used as starting materials in polymerization, AB_2 -type monomers need not be synthesized. Various hyperbranched polyimides are

synthesized because they can be obtained by polymerization using a commercial A₂-type monomer and synthesized B₃-type monomer. Hyperbranched polyimides have attracted attention as materials for gas separation membranes since the early 2000s, and most of them are synthesized by A₂- and B₃-type monomers. The gas permeability of hyperbranched polyimides is almost equal to or higher than that of other glassy polymers such as polysulfone or polycarbonate.

Hyperthermophiles

Chiara Schiraldi and Mario De Rosa

Department of Experimental Medicine, Section of Biotechnology, Medical Histology and Molecular Biology, Second University of Naples, Napoli, Italy

Hyperthermophilic bacteria and archaea have been isolated in water-containing volcanically and geothermally heated environments situated mainly along terrestrial and submarine tectonic fracture zones and represent the organisms at the upper temperature border of life. In fact they reproduce and grow between 80 and 115 °C. Hyperthermophiles have also been isolated from hot industrial environments (e.g., the outflow of

geothermal power plants and sewage sludge systems), and deep-sea biotopes present also high hydrostatic pressures (up to 360 atm); thus, the isolated species are even barophilic (Vieille and Zeikus 2001). The most heat-resistant microorganisms isolated up to date are the anaerobic archaea. The first to be identified (1960s), *Sulfolobus acidocaldarius*, a hyperthermophile and an acidophile, was found in an acidic hot spring in Yellowstone National Park, Wyoming. Since then, more than 50 hyperthermophiles have been isolated. For example, *Pyrolobus fumarii*, isolated in proximity marine hydrothermal vents, is a nitrate-reducing chemolithotroph growing in the temperature range of 90–113 °C. The upper temperature at which life is possible is still unknown, but above 110 °C, amino acids and metabolites become highly unstable. The mechanism at the base of adaptation and survival of microbes to high temperatures recently proved to involve DNA transfer (van Wolferen et al. 2013), and DNA repair through this mechanism, between the domains of bacteria and archaea, seems to have played a major role, also via homologous recombination Figs. 1 and 2. These microorganisms, because of the extreme niches in which they thrive, are adapted to distinct environmental factors including composition of minerals and gases, pH, redox potential, and salinity; most biotopes of hyperthermophiles are essentially anaerobic. Interestingly, at ambient temperatures, although unable to grow, hyperthermophiles can survive for many years by “freezing” their metabolic activities. Hyperthermophile communities are complex systems of primary producers and decomposers of organic matter. The former are chemolithoautotrophs (i.e., sulfur oxidizers, sulfur reducers, and methanogens). Because of the extremely low organic matter content of their submarine environments, hyperthermophilic heterotrophs typically obtain their energy and carbon from complex mixtures of peptides derived from the decomposition of primary producers. A few species are able to use polysaccharides (e.g., starch, pectin, glycogen, and chitin). In laboratory-scale cultivation, they needed complex medium components; hyperthermophiles reached very low cell densities, unless a specific

Hyperthermophiles,**Fig. 1** Membrane organization of hyperthermophilic archaea

H

membrane bioreactor was employed. Enzymes synthesized by hyperthermophiles, also called hyperthermophilic enzymes, are typically thermostable (i.e., resistant to irreversible inactivation at high temperatures) and are optimally active at high temperatures. When cloned and expressed in mesophilic hosts, they usually retain their thermal properties, indicating that these properties are genetically encoded (Schiraldi et al. 2000). However, both sequence alignments and amino acid content comparisons show close similarities with the mesophilic counterparts suggesting that it is not a single mechanism, but a small number of highly specific alterations responsible for the remarkable stability (Cobucci-Ponzano et al. 2012). The molecular mechanisms involved in protein thermostabilization reported to date include ion pairs, hydrogen bonds, hydrophobic interactions, disulfide bridges, decrease

of the entropy of unfolding, and intersubunit interactions. Among hyperthermophilic enzymes, there are many of potential industrial interest and few that already reached commercialization. For instance, a number of hyperthermophilic proteases are now used in molecular biology and biochemistry procedures (e.g., protease S from *P. furiosus* due to the broad specificity) and numerous thermophilic restriction endonucleases. Thermophilic amylopullulanases have been suggested, as alternative enzymes to replace α -amylases during starch liquefaction for producing fermentation syrups, rich in maltose, maltotriose, and maltotetraose (DP2 to DP4) (Cobucci-Ponzano et al. 2012). However, maltodextrin biotransformation at high temperature presents various advantages. Besides the established biotechnological applications, few other potentially interesting enzymes are isolated, cloned,

Hyperthermophiles, Fig. 2 Liposomes made from archaeal lipids

and characterized, among this *S. solfataricus* paraoxonase. That proved very stable may be used for detoxification of chemical warfare agents and agricultural pesticides (Merone et al. 2005).

Ideal Gas Selectivity

Johannes Carolus Jansen
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The ideal gas selectivity of a membrane, α_{ij} , is defined as the ratio of the permeability of two pure gases, measured separately under the same conditions:

$$\alpha_{ij} = \frac{P_i}{P_j} \quad (1)$$

where P_i and P_j are the permeability (or the permeance) of the two pure gases, respectively, with i being the most permeable gas. Rarely the real selectivity is equal to the ideal gas selectivity. Most commonly the ideal selectivity of a membrane is lower than the real selectivity, especially when the more permeable gas species plasticizes the polymer matrix, making it relatively more permeable for the slower species. In some cases, in particular in high free-volume polymers, strong sorption of the more permeable species may obstruct the transport of the less permeable species, making the mixed gas selectivity higher than the ideal selectivity.

In dense membranes, where transport occurs by the solution-diffusion mechanism, the

permeability is the product of the diffusivity and the solubility:

$$P = D \times S \quad (2)$$

where D is the diffusion coefficient and S is the solubility coefficient. Similarly, the selectivity can be expressed in a diffusion term and a solubility term:

$$\alpha_{ij} = \frac{D_i}{D_j} \times \frac{S_i}{S_j} \quad (3)$$

The ideal gas selectivity is an intrinsic property, specific for the membrane material and the particular gas pair. However, it is not a constant but it depends on the operation conditions temperature and pressure because both D and S depend on the temperature and on the operating pressure.

Ideal Separation Factor

Johannes Carolus Jansen
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The separation factor, SF , is a measure of the efficiency of the separation process and is determined from the ratio of the concentrations of the

more permeable gas species i and the less permeable gas species j in the permeate divided by the ratio of the same gases i and j in the feed stream:

$$SF = \frac{x_{i,p}/x_{j,p}}{x_{i,f}/x_{j,f}} \quad (1)$$

where $x_{i,p}$ and $x_{j,p}$ are the fractions of components i and j in the permeate and $x_{i,f}$ and $x_{j,f}$ are the fractions of components i and j in the feed. The separation factor is not a material property, but it also depends on the conditions of the separation process. It depends both on the membrane properties and on the driving force, which in turn depends on the pressure and on, for instance, the presence of concentration polarization phenomena, nonideal behaviour such as plasticization, coupling effect, etc.

Analogously, the ideal separation factor is the separation factor under ideal conditions. It can be calculated from the pure gas permeabilities.

IgG Purification

Nilay Bereli, Deniz Türkmen, Handan Yavuz and Adil Denizli

Department of Chemistry, Biochemistry Division, Hacettepe University, Ankara, Turkey

Owing to their use in the treatment of various diseases, such as primary and secondary immune deficiencies, infections, and inflammatory and autoimmune diseases, large number of immunoglobulin G (IgG) products is under clinical development. This requires certain protocols for purification and standardization. Affinity chromatography is the most popular technique to reach these requirements (Low et al. 2007). Staphylococcal protein A is one of the first affinity ligands with a very high specificity for IgG purification. It interacts with IgG through hydrophobic interactions and some hydrogen bonds and electrostatic interactions. Main disadvantages of protein A-containing carriers are the possible ligand

leakage that contaminates the therapeutic product, and also they are expensive and difficult to handle, sterilize, and preserve (Füglister 1989). Pseudo-specific ligands, such as histidine, tryptophan, phenylalanine, etc., can be used for the IgG purification. They are small molecules with high physical and chemical stability and low cost (Altıntaş and Denizli 2009; Türkmen et al. 2008). The interaction of histidine with IgG has been shown to be water mediated involving the combined electrostatic, hydrophobic, and charge-transfer interactions between histidine and the specific amino acid residues available on the protein surface (Bhattacharyya et al. 2003). In immobilized metal ion affinity chromatography (IMAC), the separation is based on the interaction of a Lewis acid (electron pair acceptor), i.e., a chelated metal ion, with electron donor atoms (N, O, and S) on the side groups of the surface histidine, tryptophan, and cysteine of the protein. Histidine-rich sequence-containing IgGs show an innate affinity for metal ions, and IMAC allows one-step separation of IgG (Altıntaş et al. 2007). Textile dyes bind proteins in a selective and reversible manner and can be used for antibody purification (Denizli and Pişkin 2001). Dye ligands can engage in ionic, hydrophobic, charge-transfer, and hydrogen bonding with proteins. In the thiophilic adsorption of proteins, electron donor-acceptor interactions between both functional groups present in the ligand structure and the adjacent sulfone group are the driving force for selective recognition (Bakhsipour et al. 2014). In general, specificity, rapid processing, mild operation conditions, conventional equipment, and reusability determine which technique to be used for IgG purification. The use of membranes has become indispensable for chromatographic applications in both research and industry area for the last few decades due to their relatively wide configuration for the size-, charge-, and affinity-based protein separation and purification. The pressure drop across the membranes is very low due to the large pore size. Owing to the continuous pore structure, mass transport occurs by convection rather than by diffusion. Chromatographic membranes are generally cost effective, and their scale-up is easier than the packed-bed

chromatography (Charcosset 1998). Membrane operations including ultrafiltration (Mohanty and Ghosh 2008; Rosenberg et al. 2009), dialysis (Bruce et al. 2002), and affinity membrane chromatography (Boi et al. 2009) have been demonstrated for their potential for IgG purification.

Immersion Casting

Francesco Galiano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Immersion casting is one of the most widely used methods in preparation of polymeric membranes. In this process, known as the nonsolvent-induced phase separation (NIPS) technique, the cast film is immersed in a coagulation bath, containing a nonsolvent, where the phase separation process takes place (Fig. 1). The most common nonsolvent is generally water, but aqueous solutions or pure organic solvents such as ethanol, isopropanol, or butanol can be also used. The exchange (or demixing) between the solvent, contained in the cast film, and the nonsolvent determines membrane formation by precipitation of the polymer. The cast film, after the immersion, separates into two phases: one polymer-rich phase forming the membrane matrix and one solvent-rich phase forming the pores of the membrane. Immersion casting technique is a process normally used for preparing membranes with a porous and asymmetric structure. Generally, at film surface, the pores are smaller since the phase separation occurs quickly; while at the bottom side, pores are bigger since the phase separation occurs slowly due to the tardy nonsolvent penetration. As a consequence,

Immersion Casting, Fig. 1 Cast film immersed into a coagulation medium where solvent and nonsolvent exchange occurs

the dense top layer acts as a selective barrier while the porous sublayer acts as a support giving to the membrane the mechanical resistance. The porous sublayer can exhibit different morphologies, such as spongelike or fingerlike structures, depending on the type of demixing.

A combination of factors such as the polymer concentration, the nonsolvent, and the precipitation temperature are responsible for different membrane structures. By immersion casting a range of polymeric membranes such as asymmetric porous ultrafiltration membranes and asymmetric reverse osmosis and gas separation membranes, in which the top layer is completely dense, can be produced.

Immobilized Enzyme

Immunoaffinity Membranes

Nilay Bereli, Handan Yavuz and Adil Denizli
Department of Chemistry, Biochemistry Division,
Hacettepe University, Ankara, Turkey

Immunoaffinity chromatography is a process in which the specific binding of an antigen to its specific antibody is utilized (Subramanian 2002).

The specificity of the binding makes this technique a very useful tool for the applications in which selective and strong antigen-antibody binding is advantageous. Immunoabsorption, in general, can be used for the purpose of therapy as well as preparative chromatography. Normally, the human immune system works to recognize, respond, and destroy pathogenic substances. When the ability of the immune systems to recognize foreign antigens versus healthy cells or tissues is failed, arising immune complexes, so-called autoantibodies, cause many kinds of autoimmune diseases (Massey and McPherson 2007). For example, myasthenia gravis, autoimmune hemolytic anemia and immune thrombocytopenic purpura, rheumatoid arthritis, systemic lupus erythematosus, thyroiditis, and insulin-dependent diabetes mellitus are such diseases. The immunoabsorption columns have been used for the treatment of immune diseases since the mid-1970s, in a study performed for the removal of DNA antibodies (Terman et al. 1974). Since then immunoabsorption therapy with affinity adsorbents using target specific antibodies has been increasingly utilized to remove pathogenic autoantibodies from patients' plasma (Uzun et al. 2010). Besides their use in the treatment of autoimmune diseases, immunoaffinity membranes can be used for the purification of antibodies or antigens with a high purity and also used for the selective and specific removal of toxic substances from human plasma (Denizli 2002). In such applications, membrane-based columns have advantages over traditional columns in terms of compressibility of the particles, the

fouling and slow flow rate through the column. Especially in contact with blood, stacked membrane system is desirable because of high convective transport rates without cell damage. The other desirable properties of affinity membranes are high porosity; large internal surface area; high chemical, biological, and mechanical stabilities; hydrophilicity; low nonspecific adsorption of blood proteins; and the presence of functional groups for derivatization (Denizli 2011).

Impedance Spectroscopy

Veronica Silva
Dow Water and Process Solution division at The Dow Chemical Company, Boulevard Cecilia Grierson 355, Buenos Aires, Argentina

Synonyms

Dielectric spectroscopy (DS); Electrochemical impedance spectroscopy (EIS)

Technique Description

Impedance spectroscopy (IS) technique measures the impedance (analogous to the resistance in the ideal resistor that follows Ohm's law) of a system over a wide range of frequencies. It is usually measured by applying an AC potential (or current) to an electrochemical cell and then measuring the current (or potential) response through the system. In a linear system, the current response to a sinusoidal potential will be a sinusoid at the same frequency but shifted in phase.

The corresponding expression representing the system impedance (Z) is indicated in Eq. 1, where ω is the radial frequency ($2\pi f$) and Φ is the phase shift. This equation can be graphically represented in a Bode plot, see Fig. 1. In a Bode plot, a logarithmic scale is used for the impedance and frequency magnitudes:

$$Z = Z_0 \frac{\sin(\omega t)}{\sin(\omega t + \phi)} \quad (1)$$

Also, the impedance is commonly expressed as a complex function:

$$Z(\omega) = Z_0(\cos \phi + j \sin \phi) \quad (2)$$

This complex expression is usually represented in a Nyquist plot. It displays the imaginary, $\text{Im}(Z)$, and the real, $\text{Re}(Z)$, contribution to the complex impedance. Figure 2 shows a Nyquist plot of the corresponding parallel RC circuit shown as well in the figure. The vector from the zero-point to any

Impedance Spectroscopy, Fig. 1 Bode plot

Impedance Spectroscopy, Fig. 2 Nyquist plot

point of the curve denotes the magnitude $|Z|$ and the phase shift, Φ . In Nyquist plot the frequency values are absent, but it decreases from right to left in the plot; each point in the plot corresponds to a frequency. The maximum of the semicircle equals occurs at such a frequency that $\omega RC = 1$, with $RC = \tau$ being the corresponding relaxation time.

More complex systems usually present a distribution of relaxation times, and the resulting Nyquist plot appears as a depressed semicircle, which is represented by a nonideal capacitor or constant phase element (CPE).

When alternating current (AC) is used in the measurements some other parasite currents can appear and disturb the experiment. This is why it is necessary to subtract these currents from the measure for each frequency. The “open” correction is made by measuring with the cell without any membrane system, with the cell containing air at the atmospheric pressure. The “short” correction has been made by using the same cell and arrangement, but the sample is a spiral copper wire in perfect contact with the electrodes without any AgCl coating. Finally, the “load” correction is obtained by using a sample with a known resistance. This open/short/load correction should be recorded and then taken into account during the measurements with the membrane system, in order to correct the values for each frequency ([Agilent Impedance Measurement Handbook 2009](#)).

Application to Membrane Characterization

Impedance spectroscopy is a powerful technique for membrane characterization. It is currently being used with different objectives: dielectric characterization (Montalvillo et al. [2011](#), [2014](#)), membrane resistance determination for ion-exchange membranes (Park et al. [2006](#)), and fouling characterization (Hu et al. [2014](#); Kavanagh et al. [2009](#)), among other specific applications.

In general, for the measurements, a membrane is placed in a cell with an electrolyte solution of specific concentration. In the cell, two electrodes are located at each side of the membrane surface, and an alternating current at a specific frequency is applied to the system which leads to an electrical potential developed through the membrane. The same procedure is repeated for a wide frequency range. In order to extract the membrane electric properties from these data it is necessary to associate the system to an equivalent electric circuit. For more complex systems, the difficulty relies on setting the proper equivalent circuit in order to obtain the electric parameters.

Following this procedure, the resistances and capacitances of the membrane are obtained and the thickness of the membrane can be evaluated. Also, by considering the dielectric constant of the solution and the membrane polymer, many membrane properties can be obtained as the resistance and capacitance values, and thus porosities and thicknesses can be obtained for each sub-layer separately as well as dielectric constant. The membrane is normally not damaged during EIS measurements (Benavente et al. [2005](#); Cañas et al. [2001](#); Cañas and Benavente [2002](#); Coster et al. [1996](#)).

The impedance spectroscopy (IS), or electrochemical impedance spectroscopy (EIS), is a powerful technique for characterizing electrical behavior of systems in which coupled electrical processes occur at different rates (Barsoukov and Macdonald 2005). The IS technique is able to measure quantitatively the electrical resistance in the bulk and interfacial regions of solid and liquid electrolyte materials, including membranes.

IS technique is widely used in the in situ non-destructive characterization of membranes, as well as to investigate concentration polarization and fouling phenomena (Fontananova et al. 2012; Antony et al. 2013).

In EIS experiments, a sinusoidal electrical stimulus (voltage or current) is applied over a frequency range to a pair of electrodes, and the response of the system under investigation is observed by the same or different electrodes. In the first case, the configuration is indicated as a two-probe (or two electrodes) type (Fig. 1a). If two additional electrodes are used to collect the response of the system, the configuration is indicated as four-probe (or four electrodes) type (Fig. 1b). Another possible configuration uses three electrodes, but it is usually employed to characterize only one half of an electrochemical cell, or phenomena occurring on an electrode and it will not be discussed here. The two-probe configuration is usually applied when the membrane is pressed between two solid conductive electrodes, like in the case of the membrane electrode assembly (MEA) for fuel cells (Fontananova et al. 2012).

On the contrary, if the membrane is in contact with a liquid electrolyte, the four-probe configuration is the most convenient and commonly used (Antony et al. 2013). This second configuration has the advantage to eliminate the contribution of the electrode injecting stimulus/electrolyte charge transfer resistance, from the impedance spectra, focusing the probing on the membrane and its interfaces.

The sinusoidal electrical stimulus is injected through two planar electrodes (working and counter electrode), and the response of the system to the sine wave perturbation is measured by two reference electrodes (indicated as sense and

Impedance Spectroscopy, Membrane Characterization by, Fig. 1 Schematic view of the experimental setup used for membrane characterization by impedance spectroscopy using two-probes (a) and four-probes configuration (b)

reference) using an impedance analyzer (usually a potentiostat/galvanostat combined with a frequency response analyzer) which measures voltage, current, and phase shift (Fig. 1).

In analogy to Ohm's law, the impedance is defined as (Barsoukov and Macdonald 2005):

$$Z_{(\omega)} = \frac{U_{(\omega)}}{I_{(\omega)}} \quad (1)$$

where $Z_{(\omega)}$ [Ω] is the impedance, $U_{(\omega)}$ [V] is the voltage drop, $I_{(\omega)}$ [A] is the current, and they depend on the circular velocity or circular frequency ω [rad/sec] as follows:

$$U_{(\omega)} = U_o \sin \omega t \quad (2)$$

$$I_{(\omega)} = I_o \sin (\omega t + \varphi) \quad (3)$$

where $\omega = 2\pi\nu$ and ν [sec^{-1}] is the frequency, t [sec] is the time, φ [$^\circ$] is the phase shift between voltage and current, and the subscript $^\circ$ refers to the amplitude of voltage and current in phase; j is the imaginary number $j = \sqrt{-1}$.

The impedance can be also rearranged as follows:

$$Z_{(\omega)} = |Z| \cos \varphi + j|Z| \sin \varphi \quad (4)$$

The Eq. 4 indicates that the impedance is composed of two parts, i.e., the real part:

$$Z' = |Z| \cos \varphi \quad (5)$$

and the imaginary part:

$$Z'' = |Z| \sin \varphi \quad (6)$$

The real part of the impedance is the resistance (Z'); the imaginary part is called reactance (Z'').

On the contrary of the measurement in direct current (DC), using an alternate current (AC) over a frequency range, it is possible to distinguish phenomena proceeding at different rates, like bipolar concentration polarization of an ion exchange membrane (IEM) in contact with an electrolyte solution, which induces the formation of an electrical double layer (EDL) and a diffusion boundary layer (DBL) (Sang et al. 2008).

As a consequence, the total electrical resistance is the sum of the contribution for the transport through the membrane and the interfaces.

The bipolar concentration polarization during an AC cycle, caused by the buildup and depletion of ions at the interfaces, is time dependent. The contribution of the interfacial ionic charge transfer through the interfaces layers at low frequencies is greater than at high frequencies, because at high frequencies there is insufficient time for their formation.

The experimental impedance data can be fitted with equivalent electrical circuit models able to represent the physical system and phenomena under investigation (Zhang and Spichiger 2000).

Impedance Spectroscopy, Membrane Characterization by, Fig. 2 Impedance spectra reported as imaginary (Z'') versus real part of the impedance (Z') for an ion exchange membrane: pressed between two solid electrodes (a) and separating two electrolyte solutions (b). The spectra are registered respectively with the two- and four-probe configuration, and the corresponding equivalent circuit

models are also shown. The resistor is indicated as R, the capacitor as C, and the constant phase element (a nonideal capacitor) as CPE. The subscript “m” is referring to the membrane, “ct” to the charge transfer between electrode and membrane, “m+s” to membrane plus solution, “edl” to the electrical double layer, and “dbl” to the diffusion boundary layer

The typical shape of the impedance spectra (Z'' vs. Z') in the case of an IEM pressed between two solid electrodes exhibits a distinct arc (Fig. 2a). In the case of an IEM separating two liquid electrolyte solutions, additional semicircles appear in the spectra (Fig. 2b). The corresponding equivalent circuits are also shown in Fig. 2.

At high frequencies ($\omega \rightarrow \infty$) the intercept on the real axis gives the membrane (R_m) or membrane plus solution resistance (R_{m+s}). Of course, the solution resistance can be obtained by blank experiments (without the membrane) and its contribution can be subtracted to obtain the pure membrane resistance.

At low frequencies ($\omega \rightarrow 0$), the intercept on the real axis gives the sum of membrane (plus solution, if present) and the interface resistances.

Imprinted composite membranes represent one of the various kinds of molecularly imprinted membranes. They are produced in a form of thin films or hollow fibers from at least two different materials. The preparation of imprinted composite membranes involves the surface imprinting of a preexisting support membrane with a thin imprinted polymer layer (Xu et al. 2009). This method allows to introduce specific recognition sites into the support membrane and therefore to increase its transport selectivity. In

Imprinted Composite Membranes, Fig. 1 Schematic representation of the two surface imprinting strategies

addition, the mechanical integrity of the original membrane is preserved. The preparation of these membranes is mainly performed by exploiting two different polymerization strategies: the surface grafting via photopolymerization and the surface coating via thermopolymerization. The first route allows the copolymerization of two or more photopolymerizable monomers using the light as energy source. In the case of the thermopolymerization, the energy source is represented by the heat. Depending upon the followed route, photo- or redox initiators are used to activate the original membrane surface through the formation of radical sites. The polymerization proceeds by the addition of monomer molecules to the free radical ends of the growing polymer chains.

Figure 1 reports a schematic representation of the two surface imprinting strategies.

Composite thin imprinted membranes are also prepared by simple deposition or of imprinted polymer particles on the surface of microfiltration membranes. Cross-flow filtration can be also used to form the surface polymer layer.

A particular type of composite membranes is prepared by means of the “hybrid molecular imprinting.” This approach envisages the incorporation of a previously synthesized imprinted polymer particles into a typically used polymer matrix and the subsequent membrane formation via the phase inversion technique (Ulbricht 2004). These kinds of membranes (also called hybrid imprinted membranes) are highly selective and

exhibit higher performance with respect to membranes directly prepared with the imprinted polymer (Donato et al. 2013).

The first imprinted composite membrane was prepared in 1997 (Wang et al. 1997) using as support matrix a poly(acrylonitrile) membrane. A molecularly imprinted layer on the membrane surface was formed by means of the UV-initiated photo-copolymerization of acrylic acid and *N,N* methylenebisacrylamide. Theophylline was used as template molecule.

Due to the mechanical and chemical stability in combination with high performance, imprinted composite membranes have a large potential application, like in biosensor technology, in solid phase extraction, in microfiltration, and in enantiomeric separation.

Imprinted Polysulfone-Aldehyde Derivatized Nanofiber Membranes

Masakazu Yoshikawa

Department of Biomolecular Engineering, Kyoto Institute of Technology, Kyoto, Japan

The functionalization of aromatic polysulfones for tailoring properties in membrane applications is of great interest. Polysulfone has overall thermal and chemical stability combined with good mechanical and membrane-making qualities. Polysulfone is a stable platform for functional group attachment and a good candidate polymeric material for membranes with tailored functionalities (Guiver et al. 1999). To this end, modified polysulfones have been intensively studied in connection with chiral separation (Yoshikawa et al. 1998, 2005, 2006, 2007; Mizushima et al. 2011; Sueyoshi et al. 2012), pervaporation separation (Yoshikawa et al. 1992a, b, 1999), and selective separation of CO₂ (Yoshikawa et al. 2000).

In membrane separation, both flux and permselectivity are important factors. The enhancement of permselectivity would be relatively easily attained by application of molecular

imprinting so that molecular recognition sites, which specifically incorporate target substrate into the membrane, can be introduced into a given membrane. However, the enhancement of flux without a concurrent reduction in permselectivity is perceived to be an unsolved problem or an unsolvable problem in membrane separation. In other words, flux and permselectivity often show a trade-off relationship. Membranes with high surface area and high porosity would be expected to break such a trade-off relationship between flux and permselectivity. Nanofiber membranes are expected to simultaneously give both high flux and high permselectivity. To this end, nanofiber membranes with molecular recognition sites, which are called molecularly imprinted nanofiber membranes, were fabricated by simultaneously applying an alternative molecular imprinting and an electrospray deposition (Sueyoshi et al. 2010; Yoshikawa et al. 2007). Those studies revealed that molecularly imprinted nanofiber membranes gave high flux without a concurrent reduction in permselectivity. A breakthrough in membrane separation was attained; in other words, membrane morphology in the form of molecularly imprinted nanofiber fabric was one of the suitable membrane forms to solve a trade-off relationship in membrane

separation. Molecularly imprinted nanofiber membranes and usual molecularly imprinted membranes were fabricated from polysulfone with aldehyde group (PSf-CHO) and print molecules, and their membrane performances, such as adsorption selectivity, permselectivity, and flux, were studied (Sueyoshi et al. 2012).

PSf-CHO with degree of substitution of 0.50 and 1.00 were adopted as candidate materials, and the derivative of D- or L-glutamic acid was applied as a print molecule to obtain molecularly imprinted nanofiber membranes and usual molecularly imprinted membranes for optical resolution (Figs. 1 and 2).

The membranes molecularly imprinted by Z-D-Glu incorporated the D-isomer of glutamic acid (Glu) in preference to the corresponding L-isomer and vice versa. In other words, the membrane imprinted by the L-isomer selectively adsorbed the L-isomer.

Figure 3 shows the adsorption isotherms of D-Glu and L-Glu for the Z-D-Glu molecularly imprinted nanofiber membrane as an example of adsorption isotherms. The adsorption isotherm of D-Glu, which was preferentially adsorbed in the membrane, shows a dual adsorption isotherm. It consists of nonspecific adsorption and specific adsorption on the specific recognition site, which was constructed by the presence of a print molecule during the membrane preparation process. Contrary to this, L-Glu, which was nonspecifically adsorbed in the membrane, gives a straight line passing through the origin.

Time-transport curves of racemic Glu through the D-isomer molecularly imprinted nanofiber membrane are shown in Fig. 4. As often observed, the transport of the enantiomer preferentially incorporated into the membrane was retarded by a relatively strong interaction between the enantiomer and the membrane. As a result, the antipode was selectively transported. Such discrepancy between adsorption selectivity and permselectivity is often observed in chiral separation.

Table 1 summarizes membrane performances for two types of molecularly imprinted membrane. As can be seen, the fluxes through the molecularly imprinted nanofiber membranes gave one to two orders of magnitude higher than those of usual molecularly imprinted membranes without depression of permselectivity.

As proved in the previous studies (Sueyoshi et al. 2010; Yoshikawa et al. 2007), the present study revealed that molecularly imprinted nanofiber membranes gave high flux without depression of permselectivity. The emergence of molecularly imprinted nanofiber membrane would solve a trade-off relationship in membrane separation (Yoshikawa et al. 2011).

Imprinting

Masakazu Yoshikawa¹ and Kalsang Tharpa²

¹Department of Biomolecular Engineering, Kyoto Institute of Technology, Kyoto, Japan

²Department of Chemistry, University of Mysore, Mysore, India

Imprinting, which is often called “molecular imprinting,” is a facile way to introduce molecular recognition sites into polymeric membranes (materials) (Sellergren 2001; Komiyama et al. 2003; Alexander et al. 2006). In other words, the molecular memory, such as a shape of the target molecule and an alignment of the functional moieties to interact with those in target

molecule, is memorized in the polymeric membranes (materials) for the recognition or separation of target molecule from others during the formation of polymeric membranes (materials).

Such molecularly imprinted materials are prepared by adopting two ways; one is “molecular imprinting,” the other “alternative molecular imprinting.” The former is a pioneering method to prepare polymeric materials with molecular recognition sites from functional monomer, crosslinker, and print molecule (template) (Wulff and Sarhan 1972; Arshady and Mosbach 1981); the molecular imprinting is further divided into two methods, covalent molecular imprinting (Wulff and Sarhan 1972) and non-covalent molecular imprinting (Arshady and Mosbach 1981) as schematically shown in Fig. 1. The latter is an alternative way to obtain polymeric membranes bearing molecular recognition sites directly from candidate polymeric materials and print molecule (Yoshikawa et al. 1995, 2011). The scheme of the alternative molecular imprinting is shown in Fig. 2. In Step 1, the polymeric material, which is a candidate material to construct molecular recognition sites, is interacted with a print molecule by specific interaction before and during the formation process of molecular recognition materials so that molecular memory can be introduced into the polymeric materials. In Step 2, the print molecule is extracted from the molecularly imprinted materials. When the molecularly imprinted material thus constructed is in contact with the print molecule or print molecule analogue, the molecular recognition sites preferentially interact with them or incorporate them into the molecular recognition sites (Step 3 and Step 4). Contrary to the pioneering molecular imprinting method, molecular recognition sites are formed at the same time as the molecularly imprinted materials are prepared from polymer solution or polymer melt. In other words, any polymeric materials, such as synthetic polymers, oligopeptide derivatives, derivatives of natural polymer, and natural polymers, can be directly converted into molecular recognition material by applying the alternative molecular imprinting (Yoshikawa 2001).

Imprinting, Fig. 1 Schemes of the covalent and non-covalent molecular imprinting (Cited from Yoshikawa et al. 2011 with permission. Copyright 2012 Elsevier Inc.)

Imprinting, Fig. 2 Scheme of the alternative molecular imprinting (Cited from Yoshikawa et al. 2011 with permission. Copyright 2012 Elsevier Inc.)

The similar approach was proposed by Michaels et al. in 1962 (Michaels et al. 1962). This study is the first report on the alternative molecular imprinting and the first application of molecularly imprinted polymeric membranes to membrane separation. Michaels' paper is the commemorable paper in molecular imprinting and membrane separation. In addition to this, molecularly imprinted polymeric membranes prepared by non-covalent molecular imprinting was reported in 1990 (Piletskii et al. 1990).

Since then, various molecularly imprinted membranes were studied by adopting non-covalent molecular imprinting. A wet phase inversion process was applied to an alternative molecular imprinting to prepare asymmetric membranes (Trotta et al. 2002).

As described above, applying molecular imprinting, such as conventional molecular imprinting or alternative molecular imprinting, molecular recognition sites are easily introduced into polymeric membranes (Ulbricht 2004). From

this, it is easy to enhance permselectivity of a given membrane by applying those molecular imprinting techniques. The enhancement of flux without a reduction in permselectivity is indispensable so that molecularly imprinted membranes can be applicable to industries.

Molecularly imprinted membranes with a higher surface area and a higher porosity are required to give higher flux and permselectivity. Electrospun nanofiber membranes with molecular recognition sites is a suitable or the best membrane morphology to attain high flux and high permselectivity. Possibility of the enhancement of flux without a concurrent reduction in permselectivity was proved by molecularly imprinted nanofiber membranes, which were fabricated by simultaneously applying an electrospray deposition and an alternative molecular imprinting (Yoshikawa et al. 2011).

Industrial/Tannery Wastewater Treatment Using Membrane Bioreactors

► Membrane Bioreactors for Treatment of Tannery Effluents

Inert Membrane

Rune Bredesen
Sustainable Energy Technology, SINTEF
Materials and Chemistry, Oslo, Norway

The term inert membrane denotes that no change in chemical reaction occurs due to contact between the membrane material and the surrounding constituents. A reaction occurring between constituents A and B to form C and D can be used as an example:

If the membrane is catalytically inactive with respect to the reaction, the term inert membrane is used to describe the membrane. The presence of a catalyst, deemed not to be part of the membrane material, may yield a change in reaction 1, and the integration of such a combination of membrane and catalyst is referred to as an inert membrane reactor (IMR). The term inert membrane is therefore commonly used in connection with membrane reactors (Koros et al. 1996) to distinguish the membrane properties from those of a catalytic membrane, the latter being catalytically active. In such reactors, the inert membrane may be used for

selectively separating reaction products from the reaction for which the catalyst serves to activate. Alternatively, the inert membrane may be employed as a distributor of reactants to ensure controlled delivery to the catalytic reaction site. Classification of a membrane as inert may also depend on the operation conditions and surface properties since the actual catalytic activity depends on parameters such as temperature, surface area, and surrounding chemical composition. Thus the same membrane may, or may not, be an inert membrane depending on the conditions under which it is operated.

The interactions between an inert membrane and its surroundings typically involve surface adsorption/desorption reactions, which may be followed by other reactions necessary for transport of matter within the membrane. For example, in the case of dense polymeric membranes, incorporation of the permeant gas molecule is required on the feed side, while the reverse process is required on the permeate side (Mulder 1996). Dense inorganic membranes, in addition, require transformation of the adsorbed molecule to atomic (in the case of metal membranes (Ward and Dao 1999)) or ionic and electronic (in the case of ceramic membranes (Sirman 2006) species at the feed side, which are then able to diffuse through the bulk membrane phase. At the permeate side, the recombination of species to the same molecular form as on the feed side takes place before desorption to the gas phase. To enhance the transformation of adsorbed gas molecules to diffusing species within the membrane and, thus, contribute to higher fluxes, catalytic surface properties are usually required. Nevertheless, such membranes which although they incorporate catalytic surface reactions, they are regarded as inert membranes since the reaction is present solely as a means of sustaining transport of the gas molecule from one membrane side to the other. Another example is inert membranes for liquid separation applications, where surface hydrophilicity and hydrophobicity may completely determine the membrane transport properties. The term inert membrane is rarely used for conventional membrane separation processes; however, one may find the term inert membrane used in such phrases as “chemically

inert membrane” or “bio-inert membrane.” These expressions refer to a specific property of the membrane such as chemical stability or compatibility in the case of chemical inertness or biological inactivity in the case of bio-inertness. In these cases the term inert membrane has a somewhat different meaning than that related to the IMRs.

Inert Membrane Reactors

Rune Bredesen
Sustainable Energy Technology, SINTEF
Materials and Chemistry, Oslo, Norway

A membrane, defined as a barrier between two phases through which transport of one or several species occurs, can be made from virtually any solid or liquid material or combinations of both. Membranes are commonly divided into inorganic, polymeric, hybrid inorganic and polymeric, or as dual phase consisting of a solid phase and a liquid phase. Furthermore, the membrane may either be dense or porous with a continuous network of pores.

A *membrane reactor* (MR) is a device for simultaneously carrying out a reaction and membrane-based separation in the same physical enclosure (Koros et al. 1996). In an *inert membrane reactor* (IMR), the *inert membrane* (*link*) and the catalyst in the form of a separate solid or

Inert Membrane Reactors, Fig. 1 Inert membrane (a) with solid catalyst, (b) with liquid containing the catalyst, (c) encapsulating solid catalyst, (d) encapsulating liquid containing the catalyst

Inert Membrane Reactors, Fig. 2 (a) Membrane extractor operation, (b) membrane distributor operation

a liquid phase are contained in the reactor (Fontananova and Drioli 2010; Julbe et al. 2001; Coronas and Santamaria 1999). Figure 1 illustrates different catalyst and inert membrane combinations in an IMR. Due to the separation of membrane and catalyst in the IMR, the membrane-based process and catalytic reactions occur in sequence. This decoupling of the processes can be advantageous with respect to operation and replacement of membrane and/or catalyst compared to MRs where the membrane serves as both catalyst and membrane. The two main functions of the membrane applied in IMRs are as an extractor or a distributor (Julbe et al. 2001; Dalmon 1997) (see Fig. 2). As an extractor, the inert membrane selectively separates a reaction product or intermediate product. The advantage may be higher conversion (equilibrium-limited reactions) or/and higher selectivity (e.g., via extraction of an intermediate that would otherwise lead to subsequent unwanted

reactions). Extraction of hydrogen from hydrocarbon dehydrogenation, reforming, or water gas shift reactions, employing hydrogen selective membranes in combination with packed or fluidized catalyst beds, has been widely studied (Sanchez Marcano and Tsotsis 2002). Dehydrogenation and reforming are typically equilibrium-limited endothermic reactions, and membrane reactor applications may benefit from the use of lower operating temperature and/or higher pressure without sacrificing yield. Esterification is yet another example of catalyzed equilibrium-limited reactions where water extraction by an inert membrane is used to increase yield (Van der Bruggen 2010). As a distributor, the inert membrane delivers the reactant in a controlled manner to the catalyzed reaction taking place in the reactor compartment (Julbe et al. 2001). The typical aim is to enhance selectivity through careful addition and temperature control of exothermic oxidation and hydrogenation reactions. Some common

examples are IMR with packed catalyst bed for oxidative coupling of methane to C₂, or oxidative dehydrogenation of hydrocarbons, by addition of oxygen and hydrogenation of alkenes by hydrogen addition. For some oxidation reactions employing IMRs, the separation of the bulk of the reactants by the membrane wall lowers the explosion potential (Coronas and Santamaria 1999).

As most membrane materials are inert, the incorporation of many different types into IMRs has been studied. Cheap polymeric membranes are advantageous with respect to capital cost, high packing density, and simple sealing technology in modules. However, their low operating temperature, typically less than 100 °C, and limited chemical stability narrow the range of applications. More expensive inorganic membranes enable high temperature operation, but since stability and transport properties are usually very temperature dependent, the different inorganic membranes have a limited window of operation. Several decades of research have shown that a number of challenges still exist with respect to high temperature applications, and commercial use of IMRs is still a future prospect. To aid reaching this future prospect, mathematical modeling and simulation is required to develop IMR design and provide an understanding of the optimal operating conditions.

Inhibition Coefficient (IC)

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

In *membrane technology*, the inhibition coefficient (*IC*) refers to a coefficient indicating quantitatively the reduction of permeability (or, equivalently, reduction of permeance or flux) of a permeating species because of one or more inhibiting species (see the entry “► [Inhibition to Permeation](#)” for definition of inhibition). The most general definition of inhibition coefficient can be provided as follows:

$$[\text{Flux}]_i^{\text{Inhib}} = (1 - IC_i) \times [\text{Flux}]_i^{\text{Clean}} \quad (1)$$

Equation 1 simply states that the flux in the presence of inhibition (indicated by the superscript “*Inhib*”) is equal to the clean (i.e., inhibition-free) flux reduced by a certain factor whose value depends on the inhibition degree. According to this definition, *IC_i* approaches the unity value (flux tending to zero) for maximum inhibition, whereas it approaches zero for minimum inhibition (flux equal to clean flux). If the clean permeation flux of the generic species *i* in mixture can be described by Eq. 2:

$$[\text{Flux}]_i^{\text{Clean}} = \frac{Pe_i^{\text{Clean}}}{\delta} \times [\text{Driving Force}]_i \quad (2)$$

and, at the same time, the surface coverage of the inhibiting species is sufficiently low to fulfill the hypotheses leading to Henry’s law, then *IC* can be

defined for the species i as reported in Eqs. 3 and 4 (Caravella et al. 2010b):

$$[\text{Flux}]_i^{\text{Inhib}} = (1 - IC_i) \times \frac{Pe_i^{\text{Clean}}}{\delta} \times [\text{Driving Force}]_i \quad (3)$$

$$[\text{Flux}]_i^{\text{Inhib}} = \frac{Pe_i^{\text{Inhib}}}{\delta} \times [\text{Driving Force}]_i \quad (4)$$

where the permeability reduction is explicitly recognized as:

$$Pe_i^{\text{Inhib}} = (1 - IC) \times Pe_i^{\text{Clean}} \quad (5)$$

For hydrogen permeation through Pd-based membranes, Eq. 2 becomes Eq. 6:

$$[\text{Flux}]_{\text{H}_2}^{\text{Clean}} = A \frac{Pe_{\text{H}_2}^{\text{Clean}}}{\delta} [(P_{\text{H}_2}^{\text{Feed}})^n - (P_{\text{H}_2}^{\text{Perm}})^n] \quad (6)$$

where $P_{\text{H}_2}^{\text{Feed}}$ [Pa] and $P_{\text{H}_2}^{\text{Perm}}$ [Pa] are the hydrogen partial pressures in feed and permeate side and δ [m] the membrane thickness. In Eq. 6, the characteristic driving force is expressed by the difference of partial pressure to the power of n , which is an empirical exponent whose value represents the macroscopic effect of all the mechanisms governing the hydrogen permeation process without inhibiting species (Caravella et al. 2010a; Flanagan and Wang 2010).

Inhibition of Hydrogen Permeation Through Pd-Based Membranes by CO

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

Synonyms

CO inhibition to Pd-based membrane

For the general concept of inhibition, see the entry “Inhibition of Permeation.” Concerning the more specific case of inhibition of hydrogen permeation through Pd-based membranes by CO – which is of crucial importance for PEM-FC applications requiring a CO content in mixture lower than 10 ppm (*Fuel Cell Handbook*, 2004) – the CO adsorption on Pd-based surface does not involve thermal dissociation and, thus, is completely reversible (Conrad et al. 1974). Therefore, properly speaking, this kind of adsorption is sometimes referred to as physical adsorption or physisorption (Conrad et al. 1974; Davies and Lambert 1981; Prigge et al. 1982; Ortega et al. 1982), different from the chemical adsorption (or chemisorption), which involves, on the contrary, a chemical bond between species and surface. This characteristics cause inhibition to decrease with increasing temperature, as adsorption and desorption are faster at higher temperatures.

With the hypotheses of validity of Henry’s law for CO (i.e., sufficiently low CO surface coverage), the hydrogen permeation flux through Pd-based membranes can be written as reported in Eqs. 1 and 2:

$$\begin{aligned} J_{\text{H}_2}^{\text{Inhib}} &= (1 - IC_{\text{H}_2, n}) \times \frac{Pe_{\text{H}_2, n}^{\text{Clean}}}{\delta} \\ &\times [(P_{\text{H}_2}^{\text{Feed}})^n - (P_{\text{H}_2}^{\text{Perm}})^n] \\ &= \frac{Pe_{\text{H}_2, n}^{\text{Inhib}}}{\delta} [(P_{\text{H}_2}^{\text{Feed}})^n - (P_{\text{H}_2}^{\text{Perm}})^n] \end{aligned} \quad (1)$$

$$Pe_{H_2,n}^{\text{Inhib}} = (1 - IC_{H_2,n})Pe_{H_2,n}^{\text{Clean}} \quad (2)$$

where $IC_{H_2,n}$ [-] is the inhibition coefficient, Pe is membrane permeability, and n is an empirical exponent whose value is an indication of the interactions among the mechanisms controlling the hydrogen permeation. The subscript n indicates that both membrane permeability and inhibition coefficient depend on the value of n .

In the particular case in which the original Sieverts' law can be applied, the pressure exponent n is equal to 0.5 (indicated by the superscript "Siev"), and Eq. 1 becomes (Caravella et al. 2010):

$$J_{H_2}^{\text{Inhib}} = (1 - IC_{H_2,\text{Siev}}) \times \frac{Pe_{H_2,\text{Siev}}^{\text{Clean}}}{\delta} \times \left[\sqrt{P_{H_2}^{\text{Feed}}} - \sqrt{P_{H_2}^{\text{Perm}}} \right] \quad (3)$$

In all the reported expressions, the values of the partial pressures must be those adjacent to the membrane surface. In the absence of appreciable external mass transfer resistance (concentration polarization), these values coincide with the bulk values. However, the presence of inhibition always includes a certain level of concentration polarization, as the inhibiting species do not permeate through membrane, generating in this way an additional resistance not only on membrane surface but also in the fluid phase of the feed side.

Inhibition to Permeation

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

In physical chemistry and chemical engineering, inhibition mostly refers to a phenomenon for which one or more species prevents other species from reaching active sites of a surface by a competitive reversible site occupation. The reversibility of this phenomenon makes it different from poisoning, which affects irreversibly the considered surface.

Historically speaking, inhibition has firstly regarded the activity reduction of catalysts. However, with the development of membrane technology, the concept of "catalytic surface" has become wider, this more generally referring also to surfaces interacting with chemical species in processes of adsorption/desorption and solubilization/desolubilization from membrane surface to membrane bulk and vice versa (i.e., not necessarily involving net chemical reactions).

If the driving force promoting permeation through membrane can be represented by the pressure difference of a generic species i , the transmembrane flow rate F_i (mol s⁻¹) and flux J_i (mol m⁻² s⁻¹) are expressed by Eq. 1 in absence of inhibition (indicated by the superscript "Clean"):

$$\begin{aligned} F_i^{\text{Clean}} &= A_{\text{Mem}}^{\text{Clean}} J_i^{\text{Clean}} \\ &= A_{\text{Mem}}^{\text{Clean}} \frac{Pe_i^{\text{Clean}}}{\delta} [P_i^{\text{Feed}} - P_i^{\text{Perm}}] \end{aligned} \quad (1)$$

where P_i^{Feed} (Pa) and P_i^{Perm} (Pa) are the partial pressure of hydrogen in feed and permeate side,

δ (m) is the membrane thickness, and A_{Mem} (m^2) is the membrane area. In general, for membranes as well as for catalysts, the reduction of active sites directly corresponds to a reduction of the effective catalytic surface. From this point of view, the intrinsic membrane permeability Pe_i^{Clean} ($\text{mol m}^{-1} \text{s}^{-1} \text{Pa}^{-1}$) – i.e., the permeability evaluated in clean (inhibition-free) conditions – is not affected by inhibiting species.

However, as it is extremely difficult to know the exact amount of surface reduction due to inhibition (and, thus, not available to permeation), in some cases the inhibition effect can be dealt with by considering a reduction of permeability (Eq. 2) rather than a reduction of surface (Eq. 3).

$$\begin{aligned} F_i^{\text{Inhib}} &= A_{\text{Mem}}^{\text{Clean}} J_i^{\text{Inhib}} \\ &= A_{\text{Mem}}^{\text{Clean}} \frac{Pe_i^{\text{Inhib}}}{\delta} [P_i^{\text{Feed}} - P_i^{\text{Perm}}] \quad (2) \end{aligned}$$

$$\begin{aligned} F_i^{\text{Inhib}} &= A_{\text{Mem}}^{\text{Inhib}} J_i^{\text{Clean}} \\ &= A_{\text{Mem}}^{\text{Inhib}} \frac{Pe_i^{\text{Clean}}}{\delta} [P_i^{\text{Feed}} - P_i^{\text{Perm}}] \quad (3) \end{aligned}$$

The expressions 2 and 3 can be used under the hypothesis of low surface coverage of inhibiting species (i.e., within Henry's law hypotheses) (Caravella et al. 2010). For higher values of surface coverage due to inhibiting species, the driving force is gradually less suitable to be described by a simple function of feed and permeate partial pressure, it involving, on the contrary, more complex expressions of the partial pressure of all the species in mixture. The overall form of these expressions cannot be easily generalized, as they strongly depend on the functionality of the adsorption/desorption mechanism on the surface as well as on that of the diffusion mechanism through membrane.

Inorganic Acids Recovery by Nanofiltration

B. S. Ooi

School of Chemical Engineering, Universiti Sains Malaysia, Nibong Tebal, Pulau Pinang, Malaysia

Nanofiltration (NF) is a type of membrane which functions in a similar way to reverse osmosis, but is generally used to retain divalent ions and allow monovalent ions to pass through. Nanofiltration has been used to recover the metal or acid value from the mining and metal finishing industries. In recent years, nanofiltration has become an emerging technology for the recovery of strong acids – inorganic (mineral) acidic solutions such as hydrochloric acid (HCl), sulfuric acid (H_2SO_4), phosphoric acid (H_3PO_4), nitric acid (HNO_3), and hydrofluoric acid (HF). These acids are commonly used in the winning, electroplating, acidic pickling, and etching process. The acid strength of the solutions can be varied up to 33 wt.% H_2SO_4 , 35 wt.% H_3PO_4 , and 10 wt.% HNO_3 .

Nanofiltration is increasingly applied to separate the metal ions and at the same time recycling the acidic solutions back to the plating bath. The performance of nanofiltration in acid recovery is complicated by their exclusion mechanism of nanofiltration which includes adsorption, size exclusion, coulombic interactions, and dielectric exclusion. Due to the monovalent of proton ($1+$) and its smaller ionic radius (hydrated oxonium ion) than water, nanofiltration has relatively lower acid (proton) rejection. However, the transport of acids across the membrane also depends on their counterions. The solution pH will affect the membrane surface zeta potential and acid recovery performance. For example, if the isoelectric point of the membrane is 4, then above pH 4, the membrane will be negatively charged. Under this pH, sulfate ion will be repelled and less proton permeation is expected in order to maintain the Donnan Equilibrium in the feed stream. On the other hand, at low pH, the membrane will have net positive charge. Permeation of multivalence ions (SO_4^{2-}) will be favorable; thus proton permeation will be enhanced to maintain electroneutrality.

Inorganic Acids Recovery by Nanofiltration, Table 1 Comparative rejection data^a

Acid	RO(%)	NF(%)
H ₂ SO ₄	~98	0–10
HCl	~90	~0

^aPerformance depends on the feed concentration

Another important concerning factor in acid/metal separation is the chemical speciation problem as weak acids form neutral species under low acidic conditions. Separation of neutral acid using NF therefore will solely depend on size exclusion. Besides, the permeate flux is strongly influenced by acid viscosity and osmotic pressure. The permeate flux decreased as the acid concentration increased due to the acid viscosity.

Membrane stability is always a concerning issue for their application in acid recovery. Commercial polymeric nanofiltration membranes are typically stable in the pH range of 2–12. Membranes of interest include CK (pH 2–8)/DK (pH 2–10) (Osmonics), SeIRO MPF-34 (Koch, pH range 0–14), NF45 (Dow, pH 3–10), PVD-1 (Hydranautics), and NF-PES-10 (Nadir) (Soldenhoff et al. 2005). The report from Cleaner Production Germany shows that nanofiltration is suitable to be used for the treatment of sulfuric pickling solutions at plant trial scale. Metal concentrations of 80 g/l were achieved in the concentrate (99 % rejection), and sulfuric acid was able to pass through the membrane at a flux of 30 l/m².h to give filtrate (permeate) amounting to 250 g/l. In this process, up to 99 % of the acid residue and the water can be returned to the pickling process (Cleaner Production Germany 2004). The general rejection data of acid using RO and NF membranes are generalized in Table 1. It shows that NF is relatively poor in retaining acid compared to the RO membrane which makes it very interesting in metal/acid separation.

Inorganic Catalytic Membrane

Rune Bredeesen

Sustainable Energy Technology, SINTEF
Materials and Chemistry, Oslo, Norway

An inorganic catalytic membrane is an inorganic membrane that is catalytically active. Inorganic membranes are made from metals, ceramics, glass, and carbon and may be porous or dense. The term inorganic catalytic membrane is typically meant in the context of membrane reactors where yield is enhanced by combining a membrane separation and a catalyzed chemical reaction. Inorganic catalytic membranes can either be composed of an inherently catalytically active material or an inert membrane structure to which a catalytically active phase is added on the outer surface or inside pores (Specchia et al. 2006), see Fig. 1. In the latter case, integration of catalyst material and inorganic membrane structure is carried out by common deposition and impregnation methods such as wet (electro)chemical deposition, chemical vapor deposition, or physical vapor deposition. Since the membrane is catalytic, reaction and separation occur in parallel a feature which distinguishes it from the sequential processes of inert membrane reactors where the inert membrane and catalyst material are separated. The function of the membrane may serve as extractor, distributor, or contactor depending on application (Dalmon 1997) (see Fig. 2) and the reaction mechanism can be (electro)catalytic, photo-catalytic, or bio-catalytic. The many different concepts and envisaged applications are described comprehensively in various text books and scientific papers (Gryaznov et al. 2006; Sanchez Marcano and Tsotsis 2002; Caro 2010; Fontananova and Drioli 2010).

Inorganic Catalytic Membrane, Fig. 1 Inherently catalytic (a) porous, (b) dense membrane. Inert membrane with catalyst deposited (c) inside pores, on outer surface of (d) porous, and (e) dense membrane

Inorganic Catalytic Membrane, Fig. 2 Inorganic catalytic membrane in (a) extractor operation, (b) distributor operation, (c) flow-through contactor operation, (d) liquid–gas contactor operation

Inorganic catalytic membranes can operate at higher temperatures than their polymeric counterpart, which opens a broader window of operation as high temperature is also required for many important reactions which are limited by low yield in traditional reactors. The assembling of inorganic catalytic membranes in membrane modules may, however, give too low a catalytic surface area and limited conversion and therefore render operation less cost efficient compared to more conventional reactors. To mitigate this problem, additional catalyst can be added to the reactor volume. In order to increase efficiency, some current development activities are aimed at manufacturing inorganic thin capillary, multichannel, and hollow fiber membranes with high surface area/volume ratio.

The dual operational nature of inorganic catalytic membranes is particularly challenging since both membrane and catalytic properties must work satisfactory. Commonly encountered issues related to degradation processes such as

adsorption, poisoning, clogging, and fouling are all critical and membrane lifetime may suffer when trying to achieve the optimal trade-off between membrane and catalyst properties. Common examples of applications include hydrocarbon dehydrogenation, hydrocarbon reforming, and hydrogenation of alkenes for which hydrogen selective inorganic catalytic membranes can be used (Sanchez Marciano and Tsotsis 2002). Combination of endothermic (e.g., water splitting to produce hydrogen) and exothermic (e.g., partial oxidation of methane) reactions for integrated mass and heat transport has been demonstrated by using catalytically active oxygen permeable membranes (Caro 2010). By feeding oxygen in a controlled manner, partial oxidation of hydrocarbons to form synthesis gas, oxidative coupling of methane, and oxidative dehydrogenation reactions have been demonstrated using dense and porous inorganic catalytic membranes (Sanchez Marciano and Tsotsis 2002; Coronas and Santamaria 1999; Sammells et al. 2006). When

porous inorganic catalytic membranes are used as flow-through contactors, a forced close spatial contact between reactants and catalyst can give improved conversion efficiency compared to reactions in catalyst powder beds (Westermann and Melin 2009). Additionally, higher selectivity may be achieved due to the short and well-defined contact time between reactants and membrane catalyst. Yet in another contactor mode, the porous inorganic catalytic membrane provides a defined catalytic region for reaction and controls transport of reactants from both sides of the membrane. For example, in liquid–gas catalytic contactors, both hydrogenation and oxidative reactions have been demonstrated.

Inorganic Composite Membrane Preparation

Lidietta Giorno¹ and Heiner Strathmann²

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

Ceramic membranes to be used in micro-, ultra-, and nanofiltration as well as in pervaporation and gas separation are also prepared as multiple-layer composite structures (Burggraaf et al. 1996). A typical three-layer structure of an ultra- or nanofiltration membrane is shown schematically in Fig. 1a and as a scanning electron micrograph in Fig. 1b indicating the materials and the pore size of the different layers. The first support layer is generally prepared from a suspension of Al_2O_3 powder using an organic polymer such as cellulose or polyvinyl alcohol as a binder and to increase the viscosity of the suspension. The suspension can be processed by slip casting or extrusion into flat sheets, hollow fibers, or tubes forming the so-called green structure which is dried and converted into the final membrane by sintering at ca. 1500 °C resulting in a porous structure of $\alpha\text{-Al}_2\text{O}_3$ with an average pore diameter of 5 or more μm and an overall porosity of about 35 %. The process is indicated in Fig. 2. A second layer prepared by a so-called sol–gel process is deposited on the support layer by dip coating or filtration. The sol used in this process consists of colloidal particles as indicated in the schematic drawing of Fig. 2. The material used for the preparation of the second layer is usually $\gamma\text{-Al}_2\text{O}_3$ or TiO_2 . The pore size of this layer is in the range of 5–10 nm. Thus, the two-layer membrane can be used for micro- and ultrafiltration applications. For the separation of lower molecular weight components in nanofiltration and pervaporation a third layer is deposited. This

Inorganic Composite Membrane Preparation, Fig. 2

Porous inorganic membrane preparation scheme based on slip-casting of a ceramic powder and sintering at 1500–1800 °C

layer is also prepared by the sol–gel process. However, the sol contains an inorganic polymer as indicated in Fig. 2 which forms a polymer gel consisting of a three-dimensional network. As material for the inorganic structure TiO_2 , ZrO_2 , or SiO_2 is often used (Liebau 1988).

A suspension is a dispersion of solid particles in a liquid; a sol is the suspension of colloidal particles or polymers. The main difference between suspension and sol is the size of the dispersed particles. Suspensions are prepared from a fine powder of aluminum oxide with an average particle diameter of 5 – 10 μm . The dispersion is mixed with an organic polymer such as polyvinyl alcohol or a cellulose derivative and poured in a mold or extruded in the desired shape as a flat sheet, tube, or capillary; dried; and sintered at 1500 – 1800 °C. The process scheme is shown in Fig. 2.

One surface of the support structure is then coated again with a suspension of finer particles,

dried, and sintered again. Sometimes, more than one coating is applied to obtain the desired pore size at the surface of the membrane. The process preparing a multilayer membrane by suspensions of different particle sizes is referred to as slip coating. With the slip-coating process membranes with pore sizes down to 20 nm to be used in micro- ultrafiltration can be made. To obtain membranes with smaller pores a sol–gel process is applied and a colloidal or polymeric gel is used which is prepared by controlled hydrolysis of a metal alkoxide to a hydroxide. The process can follow two different process paths. One path is referred to as the colloidal and the other the polymeric process path. Both pathways are illustrated in Fig. 3.

In the colloidal process path a metal oxide such as aluminum oxide is dissolved in alcohol and then hydrolyzed and precipitated by addition of excess water at elevated temperature to form a stable colloidal solution. The solution is cooled

Inorganic Composite Membrane Preparation,

Fig. 3 Schematic diagram illustrating the colloidal and polymeric route of the sol–gel process used in the preparation of composite inorganic membranes

to form a gel, which is then coated on an appropriate support and sintered at ca. 800 °C. The average pore diameter obtained in the colloidal sol–gel process is in the range of 2–5 nm.

The overall process consists of three steps:

- Metal alkoxide formation: $\text{Al}_2\text{O}_3 + \text{alcohol} \rightarrow \text{Al(OR)}_3$
- Precipitation: $\text{Al(OR)}_3 + \text{H}_2\text{O} \rightarrow \text{Al(OH)}_3 \rightarrow \gamma - \text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ (Böhmite)
- Coating and sintering: $\gamma - \text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O} \rightarrow \gamma - \text{Al}_2\text{O}_3$

In the polymeric sol–gel process the metal alkoxide is only partially hydrolyzed in an alcohol solution by a controlled addition of a minimum of water. The hydroxyl groups of the alkoxide react with each other and form an inorganic/organic polymer, which forms a clear gel that is coated on the support structure. It is dried and sintered at 500 – 800 °C and further cross-linked to form a porous structure with a pore diameter of less than 1 nm. For the polymer sol–gel process often a titanium alkoxide is used which is converted into a cross-linked inorganic polymer in three steps:

- Hydrolysis of the metal alkoxide
- Polymerization and coating
- Sintering and cross-linking

Synonyms

Inorganic fouling

Inorganic scaling occurs in reverse osmosis (RO) applications and is caused by the retention of sparingly soluble mineral salts such as calcium carbonate, calcium sulfate, calcium phosphate, barium sulfate, magnesium salts, silica, etc. Due to water removal and concentration polarization (CP), the concentrations build up and can exceed the saturation level and cause scaling of the membrane surface. Membrane scaling has two pathways, namely, surface crystallization and bulk crystallization. For surface crystallization, CP causes the sparingly soluble salt concentration at the membrane surface to exceed the solubility limit. Consequently, the surface is gradually covered by the lateral growth of a crystal deposit that reduces the effective area for permeation. For fixed imposed flux, the local flux increases in order to compensate for loss of area, and this increases the local CP level which exacerbates the scale formation. In the other pathways, crystals form in the bulk phase when concentrations exceed saturation level due to high recovery (defined as fraction of feedwater removed as permeate). Crystals in suspension are then deposited on the membrane and eventually form a porous cake layer, which provides a hydraulic resistance. There are many membrane elements connected in series in a RO plant, and concentration builds up from the feed to the tail end. Scale formation is therefore more prevalent in the tail end elements of the plant. It is likely that both scaling mechanisms, surface and bulk, could occur simultaneously in a RO system. This is because a

crystal cake causes “cake-enhanced concentration polarization” (CECP) (see “[Irreversible Fouling Resistance](#)”), and the increased CP of the scale formers leads to precipitation on the membrane and within the cake.

There are several strategies to control scaling in membrane systems. Bulk crystallization can be mitigated by controlling the supersaturation level of the salts by limiting the maximum recovery in the RO system. The effect of CP on surface concentration can be manipulated by the ratio of flux to crossflow velocity, where lower CP is favored by modest flux and raised crossflow velocity. Most scale formers are more soluble at lower pH, so the injection of acid into the feed stream can provide some control. The exception to this is silica scaling which is more serious at lower pH and requires an increase in pH. If silica and calcium scalants are both present, it may be necessary to soften the feed by ion exchange to remove the calcium and then raise the pH. Scale formation can also be controlled by the use of antiscalant chemicals. These are proprietary materials, but include various molecular weight polycarboxylates and polyacrylates, usually dosed at a few ppm level. Care needs to be taken with antiscalant selection as some tend to promote biofouling.

Integrated Membrane Processes for Biofuel Production

Lan Ying Jiang

School of Metallurgy and Environment, Central South University, Changsha, China

Biofuels are important solutions to worldwide energy crisis and greenhouse effect. Their

production through chemical, physiochemical, or biochemical conversions is one of the many procedures involved in biorefinery. Due to the complexity of the conversion mechanisms and feedstocks, what are delivered in the fuel generation procedures are not highly purified fuels but a mixture of a series of organics containing the fuels in some concentration range. In fermentation process to produce liquid bioalcohols, the situation is further complicated by the existence of bacterial cells inside the yeast cultures. In this regard, integration of separation technologies to recover the biofuels, remove other components, or enhance the concentration of biofuels is indispensable to biofuel production. The separation technologies used to refine and upgrade biofuels include distillation, membrane separation, gas stripping, liquid–liquid extraction, etc. (Vane 2005). The reasons to consider membrane separation include moderate temperature, space efficiency, and easy operation.

Several types of integrated processes using membrane as key units are employed in biofuel production. In bioethanol production, an integrated membrane process as illustrated in Fig. 1 is employed (Huang et al. 2008). In achieving recovery of volatile organic compounds (VOCs) containing the alcohols from the fermentation process, hydrophobic pervaporation and membrane distillation are used. There also exist in the fermentation broth some other chemicals with higher molecular weight such as phenolics, carboxylic acids, and amino acids. Various techniques for recovery or extraction of these

value-added chemicals have already been reviewed (Schugerl 2000). Other metabolites such as carbon dioxide (CO_2) and ammonia (NH_3) can be removed easily by aeration stripping. Pervaporation or membrane distillation has the dual function of rejecting the cells and preferentially removing the VOCs, simultaneously. But more often, a microfiltration membrane is used to hold back the microbes, so that the hydrophobic membrane, the more costly unit, will not be fouled. With the above separation procedures, the fermentation process can be carried out continuously and obtain improved productivity and conversion rate. The recovered VOCs (ethanol, acetone, butanol, 2-propanol) are directly reused within other processes or further separated. In principle, gas stripping or adsorption is more accurate in discriminating these VOCs (Schugerl 2000). Upon obtaining the ethanol-enriched aqueous solution, it is dehydrated by hybrid system incorporating distillation and pervaporation. Intensive dehydration by adsorption might be performed on condition that the purity is required to be very high. Similar design of integrated process can be used in biobutanol production.

The most common way to produce biodiesel is transesterification that transforms triglyceride extracted from vegetable oil, animal fats, grease, or algae into fatty acid alkyl esters (FAME) in the presence of alcohol (e.g., methanol) and a catalyst (e.g., acid, base) (Shuit and Subhash 2012). Two major membrane separation procedures are integrated in the above process. For the real-time separation of products from the feed mixture,

Integrated Membrane Processes for Biofuel Production,

Fig. 1 Integrated membrane process for bioethanol production (Adapted from Huang et al. 2008)

porous membrane is used to retain the oil droplet larger than the pore size while allowing the alcohol, glycerol, and biodiesel to pass through. Thereafter, glycerol is removed to obtain purified biodiesel also by using porous membrane (e.g., MF), wherein the reversed micelles binding glycerol are rejected (Wang et al. 2009). If dense membrane (e.g., pervaporation) selectively transfers glycerol that is used, one-step separation can replace the above two-step separation. Following removal of glycerol, biodiesel is further purified to remove impurities such as tri-, di-, and monoglycerides, catalyst, soap, and traces of alcohol. The removal of these impurities is essential as the presence of these impurities poses great impact

on the purity and quality of biodiesel as fuel for use in compression–ignition engines.

High-temperature gasification and anaerobic digestion are major approaches for producing biogas containing H_2 , carbon monoxide (CO), carbon dioxide (CO_2), methane (CH_4), etc. The integrated process for biogas upgrading includes two parts (Shuit and Subhash 2012). The pretreatment shown in the top part removes impurities including H_2S , H_2O , other VOCs, and siloxanes mainly using adsorption and temperature swing adsorption. The treated feed is delivered to the membrane system that consists of three blocks as shown in Fig. 2. In block 1, the feed is separated into a CO_2 -enriched permeate and a CH_4 -enriched

Integrated Membrane Processes for Biofuel Production,

Fig. 2 Integrated process for upgrading biogas from anaerobic digestion (Adapted from Shao et al. 2002)

retentate. They are further enriched to 99.0 vol.% in block 2 and 97.0 vol.% in block 3, respectively.

Intermittent Feed Diafiltration

Zoltán Kovács

Department of Food Engineering, Institute of Bioengineering and Process Engineering, Szent Istvan University, Budapest, Hungary

Intermittent feed diafiltration is characterized as a batch diafiltration process in which the processed liquor is first concentrated to a predetermined volume and then diluted back

to its original volume with a diluent. This concentration–dilution sequence may be repeated several times to obtain the desired degree of separation of macrosolutes from microsolute. As a final step, an additional post-concentration may be applied to achieve the required final volume. A mathematical analysis of intermittent feed diafiltration can be found in (Wang et al. 2007).

Note that the processing scheme of intermittent feed diafiltration is basically a slight modification of the method employed by sequential dilution diafiltration (also called discontinuous diafiltration by sequential dilution).

Intrinsic Activation Energy

Renzo Di Felice

University of Genova, Genova, Italy

Transport phenomena and chemical reaction rates are influenced by temperature. This effect is reflected on the numerical value of the coefficient rate, which therefore depends on the variable temperature. Both for mass transfer coefficient and chemical reaction coefficient, various theoretical approaches have been suggested in order to predict and quantify their dependency on the temperature. However, these approaches have had limited success, and the effect of the temperature is generally obtained through experimental evidence. A generally accepted relationship linking kinetic coefficient and temperature is the Arrhenius' law, which is written as

$$k = k_0 \exp\left(-\frac{E}{RT}\right)$$

where k is the generic kinetic coefficient, E is the activation energy, R is the universal gas constant, and T is the absolute pressure.

Arrhenius' law is basically an empirical relationship which however has been found to reproduce with the satisfactory accuracy of experimental data and the effect of temperature. A small value of the activation energy E corresponds to a weak influence of the temperature on the kinetic constant, whereas a large value of the activation energy E is representative of kinetic constant strongly influenced by temperature. Just as a reference, for gas phase chemical reaction, the activation energy is normally high, in the range of 50–250 kJ/mol, while that for diffusion coefficient is less than 10 kJ/mol).

The classic way to estimate the activation coefficient from experimental data is to utilize a plot having $1/T$ on the x-axis and $\ln(k)$ on the y-axis. The slope of the best fitting curve passing through the experimental points will yield the value of the ratio (E/R) and consequently that of E .

Ion Beam Irradiation

Isabel C. Escobar

University of Kentucky, Lexington, KY, USA

Ion beam irradiation has long been recognized as an effective method for the synthesis and modification of diverse materials, including polymers (Davenas et al. 1989; Xu et al. 1995a, b). Ion beam irradiation is the bombardment of a substance with energetic ions. When the ions penetrate through the surface of a membrane, they may eliminate the tall peaks and deep valleys, resulting in an overall reduction in surface roughness (Xu and Coleman 1997). As the ions penetrate

the membrane, they lose energy to their surroundings (membrane structure) by two main processes: interacting with target nuclei (nuclear stopping) and interacting with target electrons (electronic stopping; Lee 1999).

Nuclear stopping energy losses arise from collisions between energetic particles and target nuclei (Davenas et al. 1989; Lee 1999). Atomic displacement occurs when the colliding ion imparts energy greater than certain displacement threshold energy. If the energy is not great enough for displacement, the energy dissipates as atomic vibrations known as phonons. The threshold energy is the energy that a recoil requires to overcome binding forces and to move more than one atomic spacing away from its original site. The interaction of an ion with a target nucleus is treated as the scattering of two screened particles since the nuclear collision occurs between two atoms with electrons around protons and neutrons. Nuclear stopping varies with ion velocity as well as the charges of two colliding atoms, as it is derived with consideration of the momentum transfer from ion to target atom and the interatomic potential between two atoms.

Electronic stopping energy losses arise from electromagnetic interaction between the positively charged ions and the target electrons (Lee 1999). There are two mechanisms: one is called glancing collisions (inelastic scattering, distant resonant collisions with small momentum transfer), which are quite frequent, but each collision involves a small energy loss (<100 eV), and the other is called knock-on collisions (elastic scattering, close collisions with large momentum transfer), which are very infrequent, but each collision imparts a large energy to a target electron (>100 eV). Both collisions transfer energy in two ways: electronic excitation and ionization. Excitation is the process in which an electron jumps to a higher energy level, while in ionization an orbital electron is ejected from the atom.

Various gaseous molecular species are released during irradiation. The most prominent emission is hydrogen, followed by less abundant heavier

Ion Beam Irradiation,

Fig. 1 Typical consequences induced by ion irradiation, which include electronic excitation, phonons, ionization, ion pair formation, radical formation, and chain scission

molecular species, which are scission products from the pendant side groups and chain-end segments, and their reaction products (Lee 1999). Figure 1 illustrates various functional chemical entities created by irradiation. Cross-linking occurs when two free dangling ion or radical pairs on neighboring chains combine, whereas double or triple bonds are formed if two neighboring radicals in the same chain combine. It has been well established that mechanical, physical, and chemical property changes in polymers are determined by the magnitude of cross-linking and scission and that cross-linking enhances mechanical stability while scission degrades mechanical strength (Lee et al. 1996). The intensive energy deposition in polymers can lead to the following: (1) formation of volatile molecules and free radicals which leave defects in the polymer matrix, (2) creation of additional cross-linking between polymer chains, (3) formation of new chemical bonds, and (4) chemical reactions with chemical atmosphere such as oxidation (Lee 1999). These

four events can, in turn, lead to membrane microstructure alterations.

Ion-Exchange Membrane Characterization

Lidietta Giorno¹, Enrico Drioli^{1,2,3,4} and Heiner Strathmann⁵

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

³WCU Energy Engineering Department, Hanyang University, Seoul, S. Korea

⁴Center of Excellence in Desalination Technology, King Abdulaziz University, Jeddah, Saudi Arabia

⁵Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

Characterization of ion-exchange membranes is closely related to their preparation. The most interesting properties of ion-exchange membranes are (Spiegler 1958):

- The electrical resistance in different electrolyte solutions
- The type and density of fixed charges and their distribution in the membrane matrix
- The permselectivity of the membrane for different ions
- The transport rate of neutral components, especially water
- The mechanical and chemical stability and the swelling in different electrolyte solutions

A series of procedures and techniques are applied to determine the different membrane properties. Microscopic examination yields information on heterogeneity of the membrane structure and in case of reinforced membranes the type of reinforcement used. The electrical charge of an ion-exchange membrane can be determined qualitatively by using indicator solutions. A drop of a 0.05 % solution of methylene blue and methyl orange on a membrane sample stains a yellow

spot on top of an anion-exchange membrane and a deep blue spot on top of a cation-exchange membrane, respectively. For a quantitative characterization, more complex procedures such as the determination of the ion-exchange capacity or the electrical resistance and transport properties for different ions of the membrane are applied. Additional information can be obtained by impedance spectroscopy and chronopotentiometric measurements or from the determination of osmotic and electroosmotic water transfer. Bipolar membranes are further characterized in terms of the water dissociation capability and salt leakage under operating conditions (Strathmann et al. 1993).

Hydraulic Permeability of Ion-Exchange Membranes

Hydraulic permeability measurements provide information on the diffusive or convective transport of components through a membrane under a hydrostatic pressure driving force. In most practical applications of electrodialysis, the hydraulic permeability due to diffusion plays a minor role for the overall performance of the membrane in a given process. However, for the determination of pinholes in ion-exchange membranes will affect the performance of a membrane severely in applications with a hydrostatic pressure differences across the membrane. Pinholes can be detected quickly by placing a wet membrane sheet on a sheet of white absorbent paper. Then, a 0.2 % solution of methylene blue for an anion-exchange membrane or a 0.2 % solution of erythrosin B for a cation-exchange membrane is spread over the entire surface of the membrane. If no spots of the dye can be observed on the paper, the membrane is free of large pinholes. The hydraulic permeability of the membrane is determined at room temperature using deionized water and a hydrostatic pressure driving force in a conventional filtration cell as used in reverse osmosis or ultrafiltration experiments. The permeability can then be calculated from the volumetric flow rate.

The economics of processes using ion-exchange membranes in different applications

is determined to a large extent by the chemical stability of the membranes under process conditions. Generally, the changes in membrane properties are time and temperature dependent. Reliable information about the long-term stability of the membranes is of importance for a process design and cost calculation. For a fast evaluation, membrane samples are exposed to oxidizing agents or acids and bases and other chemical components in much higher concentration and at higher temperature than expected in practical use. Structural mechanical changes are determined by visual or microscopic investigation and standard mechanical and electrochemical tests comparing exposed with unexposed membrane samples. Since the useful life of membranes under process conditions is generally in the range of a couple of years, membrane stability tests are very time consuming. However, in many cases long-term pilot plant tests are mandatory to get a reliable estimation of the life of the membranes in practical applications.

The performance of ion-exchange membranes in the various processes is determined to a very large extent by their electrochemical properties. Therefore, a major task in characterizing ion-exchange membranes is the determination of their electrochemical properties such as the fixed charge density, the electrical resistance, the ion permselectivity, and the transport of nonionic components such as water or of other neutral molecules under operating conditions.

The Ion-Exchange Capacity of a Membrane

The ion-exchange capacity of membranes is a crucial parameter which affects almost all other membrane properties. It is usually expressed in milliequivalent per gram of dry membrane. Experimentally, the ion-exchange capacity of strong acidic or strong basic ion-exchange membranes is readily determined by titration with NaOH or HCl, respectively. For these tests, cation- and anion-exchange membranes are equilibrated in 1N HCl or 1N NaOH, respectively, and then rinsed free from chloride or sodium ions with deionized

water. The ion-exchange capacity of the samples is determined by back titration with 1N NaOH or 1N HCl, respectively. Weak base anion-exchange membranes are characterized by equilibration in 1N NaCl and titration with standardized 0.1N AgNO₃ solution. The samples are then dried, and the ion-exchange capacity is calculated based on the dry membrane. The accuracy of the measurement depends on the complete exchange of ions in the membrane which can take some time. The concentration of the fixed ion in commercial membranes is in the range between 1 and 3 milliequivalent per gram. The experimentally measured ion-exchange capacity of a membrane is an average value assuming that the ions are homogeneously distributed over the entire polymer matrix. In many heterogeneous membranes, such as most of the perfluorinated cation-exchange membranes, the fixed ions are clustered, and the local fixed ion concentration may be significantly higher than the average value.

Determination of the Electrical Resistance of Ion-Exchange Membranes

The electrical resistance of ion-exchange membranes is an important parameter determining to the energy consumption in electrodialysis (Strathmann et al. 2006). The specific membrane resistance is usually reported as Ω cm or Ω m. From the engineering point of view, the membrane area resistance in units of Ω cm² or Ω m² is more useful and generally given in the literature describing commercial products. The electrical resistance of a membrane is determined by the ion-exchange capacity and the mobility of the ion within the membrane matrix. The ion mobility in the membrane depends strongly on the nature of the mobile and fixed ion species. It is furthermore affected by the temperature.

The area resistance of ion-exchange membranes can be determined by direct current (DC) or alternating current (AC) measurements. In DC measurements the membrane is installed in a cell which consists of two chambers containing the test solution separated by the test membrane as indicated in Fig. 1.

Ion-Exchange Membrane Characterization, Fig. 1 Schematic drawing of a test cell for determining the resistance of ion-exchange membranes with direct current

The two electrodes used to provide the electrical potential driving force to obtain a certain current are separated by membranes from the test solution to avoid gas bubbles to disturb the measurement. As test solution a 1 or 0.5 mol/L Na_2SO_4 solution is used. The same solution is also used to rinse the electrode chambers and remove the gases produced at the electrodes. The actual potential drop in DC measurements across the membrane is determined with calomel electrodes attached to Haber-Luggin capillaries placed with their tips close to the membrane surface. The potential drop between the Haber-Luggin capillaries is measured with and without the membrane in the test cell as a function of the current density passing through the cell. The resistance is given by the slope of the current versus the voltage drop curve. To obtain the membrane resistance, the resistance of the cell without the membrane is subtracted from the resistance of the cell with the membrane.

The area resistance is given by:

$$r_{m+s} = RA_m = \frac{U}{i} \quad (1)$$

The membrane resistance is:

$$r_m = r_{m+s} - r_s \quad (2)$$

Here R is the resistance, A_m is the area of the membrane, U is the voltage drop measured between the Haber-Luggin capillaries and i is the current density, r_{m+s} and r_s are the area resistances of the cell with and without the membrane between the Haber-Luggin capillaries, and r_m is the area resistance of the membrane.

The determination of the membrane resistance by direct current measurements is quite accurate as long as the position of the Haber-Luggin capillaries is as close as possible to the membrane and kept identical in the test with and without the

Ion-Exchange Membrane Characterization,

Fig. 2 Schematic drawing of a test cell used for membrane resistance measurements using alternating current

membrane. To avoid boundary layer effects, the bulk solution must be well mixed. But even if the boundary layer effects are well controlled, the direct current measurements are always connected with a transport of ions resulting in a concentration change in the electrolyte solution at the membrane surface which affects the accuracy of the measurement.

Concentration changes at the membrane surface are avoided in resistance measurements with alternating current. A typical test cell used for resistance measurements with alternating current is shown in Fig. 3. The membrane resistance is determined from resistance measurements in a cell with and without membrane. The resistance of the membrane can be calculated from the following relation:

The area resistance r_m is related to the specific resistance by:

$$r_m = \rho_{m+s}(d_m + d) - \rho_s d \quad (3)$$

Here r_m are the area resistances of the membrane, ρ_{m+s} and ρ_s are the specific resistances of the cell with and without the membrane, and d_m and d are

Ion-Exchange Membrane Characterization,

Fig. 3 Equivalent resistance-capacitance circuit for a simple membrane in an electrolyte solution neglecting electrode resistances and capacities

the thickness of the membrane and the distance between the electrodes.

The specific resistance ρ is:

$$\rho = R \frac{A_m}{d} \quad (4)$$

Here A_m is the cross-sectional area of the cell as indicated in Fig. 2 and R is the resistance measured between the electrodes.

For an accurate determination of the membrane resistance, it is important that the difference between the measurement of the cell resistance with and without a membrane is as large as possible. Since the specific resistances of the membrane and the electrolyte solution are in the same

order of magnitude and the membrane thickness d_m is small, the distance d has to be as small as possible.

Comparing the direct and alternating current membrane characterization processes often significant differences in the measured resistances of more than 50 % is often observed. The alternating current measurements give a much lower membrane resistance than the direct current measurements. This is a general finding. However, the magnitude of the difference in the results depends on the membrane structure. In very heterogeneous membranes, the difference is larger than in more homogeneous membrane structures. The reason for the different results is that in direct current measurements, the ions are physically transported through the membrane matrix, whereas in alternating current measurements, the ions are only oscillating around their locations. Assuming the structure of an ion-exchange membrane consists of a microscopic scale of a solid neutral polymer phase and electrolyte-filled pores, then the mobility of the ions in the pore liquid is high. But their transport through the membrane is hindered by the solid polymer structure which acts as a bottleneck between pores. This type of structure is typical for fluorocarbon membranes. In alternating current measurements, the transport of the ions on a very small scale, i.e., in a pore, is measured. In direct current measurements, the transport of the ions is measured on a macroscopic scale which includes also the passage through a bottleneck between electrolyte-filled pores. The direct current and alternating current difference is treated in detail in the literature (Zabolotsky and Nikonenko 1993).

A rather simple and reliable method of measuring resistances is based on impedance spectroscopy. The difference between the alternating current resistance measurements and the impedance spectroscopy is that in the first case, the frequency of the alternating current is kept constant, while in impedance spectroscopy the frequency of the alternating current is changed, and the response to the changing frequency is determined by a spectrometer.

Ion-exchange membranes display a variety of electrical properties that suggest that they can be modeled as a combination of electrical analog components. For example, an applied potential can produce a current flow through the membrane, and this is indication that the membrane has a finite resistance. In addition, the charged groups at the membrane/solution interface provide sites for the redistribution of charges at the membrane surface when the potential is changed. This charge redistribution is similar to that observed for a capacitor in which a potential change produces a change in the net charges. The electrolyte solutions and the electrodes on both sides of the membrane also have a certain resistance. The properties of the ion-exchange membrane, the solution, and the electrodes can be described electrically by an equivalent circuit as indicated in Fig. 3, where C_m and R_m are the membrane capacitance and resistance, respectively, and R_s is the resistance of electrodes and the electrolyte solution.

To determine membrane resistances by impedance spectroscopy, the entire system, i.e., the membrane, the electrolyte, and the electrodes, is treated as a "black box." An alternating sinusoidal voltage of a given frequency and amplitude is applied to the system. The resulting current is measured, and then the phase shift compared to the input signal is determined. The procedure is repeated at different frequencies (see entry "Impedance Spectroscopy, Membrane Characterization by).

Ion-Exchange Membrane for Fuel Cells

Antonino Salvatore Arico
CNR-ITAE Institute, Messina, Italy

Low-temperature fuel cells can be equipped with a proton or anion exchange membrane in alternative to liquid electrolytes (Aricò et al. 2001). The core of a polymer electrolyte fuel cell (PEMFC) is the ion exchange membrane. The electrodes (anode and cathode) are in intimate contact with the membrane faces. The membrane determines the fuel cell resistance and the fuel permeation rate, and it influences the reaction rate. It is well known that the use of non-noble metal catalysts is possible in the presence of alkaline electrolytes. Protons conducting electrolytes have been preferred to alkaline electrolytes for several decades for practical reasons, e.g., to avoid carbonation. The standard electrolyte membrane is usually a perfluorosulfonic acid membrane such as Nafion. Most of the electrolytes alternative to Nafion both proton conducting and alkaline type, e.g., hydrocarbon type, are significantly cheaper, and in some cases, they are also characterized by smaller hydrogen and methanol crossover. However, lifetime characteristics similar to those shown by Nafion-type membranes in fuel cells have not yet been demonstrated for the alternative membranes. Concerning with the conductivity, only recently, membrane alternative to Nafion type have shown similar levels of performance. One critical aspect is related to the fact that the presence of water is a requirement of low-temperature PEMFCs and DMFCs for the occurrence of the electrochemical reactions and to promote ion conductivity (water-assisted conductivity mechanism). High ionic conductivities are often associated to the presence of large water uptake by the membrane, but this property often causes poor mechanical characteristics such as large swelling and relevant crossover (especially methanol). Phosphoric acid-doped polybenzimidazole membranes use a

Grotthus mechanism of proton transport and do not require water (Wang et al. 1995). These membranes operate at about 180–200 °C. Whereas composite perfluorosulfonic acid membranes or sulfonated hydrocarbon including inorganic fillers such as silica rely on the water-assisted mechanism, they can operate up to 145 °C, under particular conditions (3 bar abs pressure), due to the enhanced water retention of the filler (Aricò et al. 2003).

Composite recast Nafion® membranes containing inorganic fillers have been employed in high temperature (~150 °C) direct alcohol (Aricò et al. 1998) and H₂-air fuel cells (Watanabe et al. 1996). These composite membranes were originally developed for reduced humidification operation in polymer electrolyte fuel cells (Watanabe et al. 1996) due to the enhanced water retention inside the membrane by the effect of the inorganic filler (Aricò et al. 1998). A further advantage of composite membranes relies in the barrier effect given by the inorganic filler for methanol crossover (Ren et al. 1996).

Ion-Exchange Membrane Preparation

Seung-Hyeon Moon

School of Environmental Science and Engineering, Gwangju Institute of Science and Technology (GIST), Gwangju, South Korea

Definition

An ion exchange membrane is a membrane through which ions permeate selectively between two aqueous phases by diffusion or electromigration. Ion exchange membranes are prepared with polymeric materials, inorganic salts, or composite materials. This entry describes the preparation of ion exchange membranes mostly based on polymeric materials. Like other membranes, an ion exchange membrane should have a high flux and a high selectivity, often characterized by electrochemical properties representing transport of ions. The desired properties of ion exchange membranes are (i) high ionic conductivity, (ii) high transport number, (iii) good mechanical stability, and (iv) high chemical and thermal stability. Ion exchange membranes are prepared by binding ion exchange functional groups on the polymer backbone with or without supporting matrix. Therefore, the main components of ion exchange membrane fabrication are polymer material for a base membrane, functional groups, and supporting matrix.

Base Membrane

The polymers used for ion exchange membranes are polyethylene, polystyrene, poly(vinylimidazole), poly(acrylonitrile), polyphosphazene, polysulfone, poly(ether ether ketone), poly(phenylene oxide), etc. (Sata 2004). The polymer is selected based on possibility of functionalization, polymer processability, chemical and mechanical stability, and compatibility with supporting matrix.

A polymeric base membrane is formed as a sheet by casting a polymer solution or polymerization of monomers appropriately. Polymerization is carried out by heat and/or UV radiation with initiators. Various fabrication processes have been developed such as sandwich method, latex method, block copolymerization, paste method, and graft polymerization (Tanaka 2007). The thickness of a base membrane is about 100–200 μm , thinner membranes being developed for low electric resistance. When an ion exchange membrane is used under harsh conditions such as extreme pH or high electron activity, hydrogen atom in the polymer backbone is easily attacked, causing degradation of the membrane. Common approaches to eliminate the α -hydrogen are uses of fluorinated polymers, aromatic chain polymers, and sulfone group.

Functionalization

The base membrane is to be functionalized by sulfonation for a cation exchange membrane (CEM) or by amination for an anion exchange membrane (AEM). Frequently used sulfonating reagents are sulfuric acid, chlorosulfuric acid, a mixture of sulfuric acid and chlorosulfuric acid, dioxane- SO_3 complex, and pyridine- SO_3 complex. Also a base membrane is functionalized with aminating agents such as trimethylamine (TMA), triethylamine (TEA), 1,4-diazabicyclo[2.2.2]octane (DABCO), *N,N,N,N*-tetramethylethylenediamine (TMEDA), and tris(2,4,6-trimethoxyphenyl)-phosphine (TTMPP) to make an AEM (Toshikatsu et al. 2004). Typical functional groups on polymer backbones for CEMs are SO_3H , $-\text{COOH}$, $-\text{PO}_3\text{H}_2$, phenolic OH, $\text{C}(\text{CF}_2)_3\text{OH}$, and $-\text{CF}_2\text{SO}_2\text{NHR}$, and those for AEMs are $-\text{NH}_2$, $-\text{NH}$, $-\text{aniline}(\text{NH}_2)$, $-\text{N}(\text{CH}_3)_3\text{OH}$, $-\text{S}(\text{CH}_3)_2\text{OH}$, and $-\text{P}(\text{CH}_3)_3\text{OH}$. Some functional groups are attached by graft methods with the help of plasma or γ -ray radiation. An amphoteric membrane contains both cationic and anionic functional groups in the polymer backbone which are interacting with counter ions differently depending on the environmental pH.

A mosaic membrane is prepared by blending cation exchange polymer and anion exchange polymer. Also ion exchange membranes can be prepared by polymerization of a monomer that contains a cationic or an anionic moiety with neutral polymer (Strathmann 2004) called pre-functionalization. Monovalent selective ion exchange membranes are prepared by coating regular ion exchange membranes with highly cross-linked polymer material or oppositely charged ion exchange layer.

Reinforcement

Often a polymeric base membrane is hydrophobic without ion exchange capacity. When the base membrane turns to an ion exchange membrane, the membrane becomes hydrophilic by ionic solvation as ion exchange capacity increases. The hydrophilicity leads to high conductivity and adverse effects such as swelling and mechanical weakness of the membrane. To improve the stability of the hydrophilic ion exchange membrane, reinforcing material is to be introduced. Chemically inert powder (e.g., PVC, SiO₂, TiO₂), nonwoven or woven fabrics (e.g., PVC, bacterial cellulose, electrospun fiber), and porous sheets (e.g., PE, PP, PTFE) are employed as reinforcing material. This type of membranes is called hybrid or composite membranes. Inorganic particles such as SiO₂ rather increase the hydrophilicity while passage of non-charged compounds is blocked effectively. Another way to strengthen the membrane is cross-linking the polymer chain, since a linear polymer chain is flexible and readily absorbs solvent including water. A frequently used cross-linking agent is divinylbenzene. In some cases polymer chains are cross-linked by condensation reaction, and functional groups are involved in the reaction at a high temperature. Generally electrochemical properties, i.e., ion exchange capacity and conductivity, should be compromised with chemical and mechanical stability in the membrane preparation with reinforcing materials.

Heterogeneous Membrane

Heterogeneous membranes are fabricated by binding ion exchange particles and cast on a plate or film. Ion exchange resin beads are ground, by a ball mill or a high speed blender, in preparing fine particles to be uniformly mixed with binder in solvent. A heterogeneous ion exchange membrane is thicker (500–1,000 μm) than a homogeneous ion exchange membrane and advantageous in mechanical strength, but exhibiting a high electric resistance.

Bipolar Membrane

A bipolar membrane is a sandwich-type ion exchange membrane made with a sheet of cation exchange membrane and that of anion exchange membrane. Practically a bipolar membrane is prepared by applying an anion exchange layer on a cation exchange membrane, or vice versa. When a bipolar membrane is prepared with prefabricated ion exchange membranes, the contacting sides should be slightly roughened to apply binder, so that the interface resistance may be minimized. Since the membrane is used for water dissociation under an electric field at an overvoltage, catalyst for the water dissociation reaction should be placed in the interface between the cation exchange layer and the anion exchange layer. Typical catalysts are soluble metal ions or insoluble metal oxides.

Porous Membrane

Usually ion exchange membranes are considered as nonporous since their pores are not controlled and ions pass through ion channel with minimized convective flow. The diameter of ion channel is known as 1–5 nm which is filled with pendant-type functional groups in an aqueous phase. While nonporous ion exchange membranes are dominantly utilized, porous ion exchange membranes are investigated for limited applications where a high flux transport is required at a slightly lower

selectivity. Such porous ion exchange membranes are prepared by phase inversion to control nanometer size pores, followed by functionalization. Alternatively pre-functionalized polymer dissolved in solvent is cast and dried in air or nonsolvent (e.g., water) to form pores in the membrane.

hydrocarbon or fluorinated hydrocarbon polymers which carry positively or negatively charged ions fixed to the polymer structure (Xu 2005; Bergsma and Kruissink 1961; Molau 1981). The type and the concentration of the fixed ions in a membrane structure determine permselectivity and the electrical resistance of a membrane, while the chemical stability and the mechanical properties of the membrane are determined mainly by the matrix polymer. There are three types of ion-exchange membranes:

- Cation-exchange membranes which contain fixed negatively charged ions and which have a selective permeability for cations
- Anion-exchange membranes which contain fixed positively charged ions and which have a selective permeability for anions
- Bipolar membranes which consist of a cation- and an anion-exchange membrane laminated together

Ion-Exchange Membranes

Heiner Strathmann

Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

Ion-exchange membranes. Most of today's ion-exchange membranes used in commercially relevant processes are 0.2–1 mm thin sheet of

The ions often used as fixed charges in cation-exchange membranes are $-\text{SO}_3^-$ and $-\text{COO}^-$.

Fixed charges used in anion-exchange membranes are $-\text{N}^+ \text{H R}_2$ and $-\text{N}^+ \text{R}_3$.

The structure of a cation-exchange membrane is illustrated in Fig. 1 which shows the polymer matrix with the fixed negative ions and the mobile counterions as well as their pathway through the membrane.

The most desired properties for ion-exchange membranes are:

Ion-Exchange Membranes,

Fig. 1 Schematic drawing illustrating the structure of a cation-exchange membrane showing fixed negative ions and mobile positive counterions in the polymer matrix

- High permselectivity – an ion-exchange membrane should be highly permeable for counterions, but should be impermeable to co-ions.
- Low electrical resistance – the permeability of an ion-exchange membrane for the counterions under the driving force of an electrical potential gradient should be as high as possible.
- Good mechanical and form stability – the membrane should be mechanically strong and should have a low degree of swelling or shrinking in transition from dilute to concentrated ion solutions.
- High chemical stability – the membrane should be stable over the entire pH range from 1 to 14 and in the presence of oxidizing agents.

For the practical preparation of ion-exchange membranes, two rather different procedures are used. The first procedure results in a homogeneous ion-exchange membrane structure and is closely related to the preparation of ion-exchange resins. Homogeneous ion-exchange membranes are produced by either a polymerization of monomers that carry anionic or cationic moieties or by introducing these moieties into a polymer which may be in an appropriate solution or a solid preformed film. The second widely used ion-exchange membrane preparation technique which leads to a rather heterogeneous structure is based on mixing an ion-exchange resin powder with a binder polymer, such as polyvinylchloride or polyethylene, and extruding the mixture as a film at a temperature close to the melting point of the polymer.

A cation-exchange membrane with exceptional good chemical and thermal stability which is widely used in the electrolytic chlorine-alkaline production and as polymer electrolyte in low-temperature fuel cell consists of a polyfluorocarbon material. This membrane is often referred to as “Nafion[®] membrane” which is the trade name of DuPont. There are several more ion-exchange membranes with special properties commercially available such as the bipolar membrane which is composed of an anion- and a cation-exchange layer laminated together (Simons 1993).

Ion-Exchange Membranes in Chlor-Alkali Process

César Valderrama

Department of Chemical Engineering, Universitat Politècnica de Catalunya-Barcelona Tech (UPC), Barcelona, Catalonia, Spain

Ion-exchange membranes in chlor-alkali process (also called ion exchange membranes in chlor-alkali membrane cell process) are the synthetic membranes employed to produce chlorine (Cl_2) and alkali, sodium hydroxide (NaOH) or potassium hydroxide (KOH) by electrolysis of a salt solution. These membranes are permeable to either positively or negatively charged ions in aqueous solution used in the chlor-alkali industry. The membranes that are selectively permeable to positively charged ions are usually named cation-exchange membranes (CEM), and membranes selectively permeable for negatively charged ions are called anion membranes (AEM). The selectivity occurs due to high concentration of immobile (fixed) ions within the membrane body.

Cation membranes have negatively charged fixed ions usually sulfonic or carboxyl groups chemically bound with the membrane's matrix. Their charge is neutralized by positively charged ions (counterions). An anion membrane would have positively charged fixed ions, usually quaternary ammonium groups, and negatively charged counterions. Fixed ions and counterions are connected by ionic bounds in a dry membrane. In the swollen membrane, this bond would be dissociated. Therefore, the counterion is mobile

Ion-Exchange Membranes in Chlor-Alkali Process, Fig. 1 Membrane cell process in chlor-alkali industry

and can be replaced by another ion. Hence the membrane would be permeable to ions with the charge sign opposite to the charge of the fixed ion. This unique property makes ion-exchange membrane applications very attractive for chemical industry, because it allows for the removal, addition, substitution, depletion, or concentration of ions in process solutions (Baker 2000; Nunes and Peinemann 2001).

The chlor-alkali (also called “chlorine-caustic”) industry is one of the largest electrochemical technologies in the world. It is an energy-intensive process and is the second largest consumer of electricity (2400 billion kWh) among electrolytic industries. The chlor-alkali industry produces chlorine and caustic solution (sodium or potassium hydroxide) simultaneously by means of decomposition of a saturated sodium chloride solution often called “brine.” Along with the chlorine and the caustic solution, hydrogen is produced. There are three basic processes for the electrolytic production of chlorine. These three processes are the diaphragm cell process, the mercury cell process, and the membrane cell process. The distinguishing difference between the technologies relies in the manner by which the anolyte and the catholyte streams are prevented from mixing with each other. Separation is achieved in a diaphragm cell by a separator and in a membrane cell by an ion-exchange membrane. In mercury cells, the cathode itself acts as

a separator by forming an alloy of sodium and mercury (sodium amalgam) which is subsequently reacted with water to form sodium hydroxide and hydrogen in a separate reactor (O’Brien et al. 2005).

The membrane cell technology has several advantages compared to the other processes: high energy efficient, high purity of caustic, and low environmental impact; the membrane process does not use highly toxic materials such as mercury and asbestos. Disadvantages of the membrane process are that the caustic soda produced may need to be evaporated to increase concentration and, for some applications, the chlorine gas produced needs to be processed to remove oxygen. Furthermore, the brine entering a membrane cell must be of a very high purity, which often requires costly, additional purification steps prior to electrolysis. Nowadays, the membrane cell process is the most used in the world, and in Europe, complete conversion to the membrane technology is expected in the next years due to the mandatory deadline (2020) to phase out the mercury cells (Euro Chlor 2011; de Bastos Vidal 2013).

In a membrane cell, an ion-exchange membrane separates the anode and cathode compartments (Fig. 1). The separator is generally a bilayer membrane made of perfluorocarboxylic and perfluorosulfonic acid-based films, intercalated between the anode and the cathode. The saturated brine is fed to the anode compartment where

Ion-Exchange Membranes

in Chlor-Alkali Process,
Fig. 2 Illustrative scheme of the structure of different commercial membranes (de Bastos Vidal 2013; Vogel and Meier-Haack 2014)

chloride ions are oxidized to chlorine gas. The sodium ions migrate through the membrane to the cathode compartment. The demineralized water added to the catholyte circuit is hydrolyzed, releasing hydrogen gas and hydroxide ions. The sodium and hydroxide ions combine to produce caustic soda which is typically brought to a concentration of 32–35 % by recirculating the solution before it is discharged from the cell. The reactions evolved in this process are the following (IPPC 2014):

At the anode:

At the cathode:

Depleted brine is discharged from the anode compartment and re-saturated with salt. If needed, to reach a concentration of 50 % caustic soda, the caustic liquor produced has to be concentrated by evaporation (using steam).

The first generation of commercial membranes (1975) was able to directly produce sodium hydroxide solutions of 2–40 wt %. They were made from fluoropolymers functionalized with sulfonic groups. These membranes were relatively thick with heavy reinforcement cloths and the electrode gap was 9 mm. Due to these membrane characteristics, the typical operating potentials were high (3.8–4.0 V at 2.5 kA/m²) that combined with low current efficiency give a DC energy consumption of 3300 kWh/ton of caustic soda. Additionally, the current efficiency decline

was quite fast due to impurities in precipitation in the membrane structure. Later on, the development of a laminated membrane structure with two different functional groups revolutionized the chlor-alkali membrane cell process by improving the current efficiency and reducing the operating potential (Navin 2002; de Bastos Vidal 2013).

Nowadays, the commercially available membranes in the chlor-alkali industry may have from one up to three layers but generally consist of two layers with a polymeric matrix made of tetrafluoroethylene. Sulfonic and carboxylic groups are used as fixed ionic groups on the anode and cathode side of the membrane, respectively (Fig. 2).

The use of different ionic groups, as illustrated in Fig. 2, has significant effects on the permselectivity and conductivity of each layer. Furthermore, the sulfonic groups are excellent proton conductors while the carboxylic groups are highly permselective to cations due to their lower water content (Sata 2000). The membranes must remain stable while being exposed to chlorine on one side and a strong caustic solution on the other. The mechanical properties of the membranes (tensile and tear strength) are greatly improved by reinforcements; a PTFE woven cloth is used to reinforce the membrane structure to prevent damage or tearing of the membrane. There are different types of cloths to reinforce the membranes and in some cases sacrificial fibers are also used. More and thinner fibers increase mechanical strength besides providing low voltage and high current efficiency. To prevent the adherence of bubbles to the membrane surface, the membrane surfaces are made hydrophilic. The

general economic lifetime of chlor-alkali membranes is approximately 3 years but ranges between 2 and 5 years (Strathmannm 2004; de Bastos Vidal 2013).

The perfluorinated membranes developed for use in chlor-alkali cells exhibit super selectivity and high thermal and chemical stability, which are not found in other classes of polymeric ion-selective membranes. There are four main manufacturers of ion-exchange membranes to the chlor-alkali industry: DuPont (Nafion membranes), Asahi Glass (Flemion membranes), Solvay Plastics (formerly Dow membranes), and Asahi Kasei (Aciflex membranes). The differences between suppliers are related to the modifications made on the polymer and on the functional groups, the type of reinforcement used, and other chemical and mechanical details (O'Brien et al. 2005).

The membranes commercially available for the chlor-alkali industry can be divided in two classes regarding their characteristics: high performance and high mechanical strength membranes. Low-resistance membranes are more adequate to narrow gap electrolyzers due to their low voltage. On the other hand, high-strength membranes are used in more robust electrolyzers where the main requirement is high physical strength. Today, membranes operate at higher current densities with current efficiencies of about 97 % producing a caustic soda stream of 32 wt %. The typical DC energy consumption values are as low as 2100 kWh/ton of caustic soda.

Ion-Exchange Mosaic Membranes

► Mosaic Membranes

Iron Oxides: Polymer Composite Membranes

Zbigniew J. Grzywna and Gabriela Dudek
Department of Physical Chemistry and
Technology of Polymers, Silesian University of
Technology (SUT), Gliwice, Poland

One of the best modification techniques for enhancing membrane performance is blending with inorganic nanoparticles such as iron oxides (Dudek et al. 2012, 2013, 2014), ZrO₂ (Gestel et al. 2006), TiO₂ (Gestel et al. 2006; Hong et al. 2013), Al₂O₃ (Hong et al. 2013), and carbon nanotubes (Gethard et al. 2011). In hybrid membranes, inorganic components are dispersed in a polymer matrix. These membranes benefit in the selectivity of active components and the simplicity of polymeric membrane processing. Particularly, the usage of inorganic-organic composite materials is becoming increasingly important due to their extraordinary properties, which arise from the synergism between the properties of the individual components as well as their interactions with the base matrix materials

(Dudek et al. 2012). The separation properties of the final composite membranes depend on component compatibility and dispersibility of the inorganic phase in the polymer matrix. Polymer grafting on the surface of the inorganic nanoparticles seems to be the best modification method for the dispersibility improving of the inorganic phase in the polymer matrix. Another surface modifiers often used for the stabilization of particles are fatty acids (oleic, lauric, palmitic, or stearic). Using those modifiers, the inorganic components could be well dispersed in polymer solutions forming uniform dispersion (Liu and Su 2005). In the case of higher concentration of inorganic phase in polymer solution, sedimentation phenomenon can be observed and further aggregation and inhomogeneous distribution, what was discussed in Dudek et al. (2012).

In recent years, the nanocomposite membranes, as a special functional material, have attracted much attention and been applied in loading of biomolecules (Nicolás et al. 2013), biosensor (Chena et al. 2012), metal adsorption (Stopa and Yamaura 2010), and others (Tsai et al. 2010). Especially, Fe_3O_4 ferrite magnetic nanoparticles (Dudek et al. 2012, 2013, 2014) have been rising as a significant useful material due to their specific properties such as superparamagnetic, nontoxic, great surface/area ratio, small size, etc. These materials exhibit novel macroscopic magnetic properties due to the combined action of quantum-sized effects, strain and surface effects, interface between nanostructures and the matrix, matrix properties, and morphologies of nanostructures. Compared to the traditional micro-sized magnetic supports used in separation process, nano-sized magnetic carriers possess quite a good performance due to higher specific surface area and lower internal diffusion resistance (Dudek et al. 2012, 2013, 2014). Iron oxide nanoparticles are being extensively exploited in several scientific and technological applications such as separation processes (Dudek et al. 2012, 2013, 2014), targeted drug delivery (Saboktakin et al. 2010), magnetic resonance imaging (Andreas et al. 2012), hyperthermia and cancer therapy (Santhosh and Ulrih 2013), water remediation (Crane et al. 2011), etc. Depending

upon the synthesis method and conditions, iron oxide can be obtained in one of several phases, such as FeO (wustite, antiferromagnetic), Fe_3O_4 (magnetite), $\text{Fe(II)Fe(III)}_2\text{O}_4$ (ferromagnetic or superparamagnetic when the size is less than 15 nm), $\alpha\text{-Fe}_2\text{O}_3$ (hematite, weakly ferromagnetic or antiferromagnetic), $\gamma\text{-Fe}_2\text{O}_3$ (maghemite, ferromagnetic), $\epsilon\text{-Fe}_2\text{O}_3$, and $\beta\text{-Fe}_2\text{O}_3$ (Si et al. 2008), among which magnetite and maghemite are the very promising and widely tested candidates for separation application.

The presence of magnetic particles in polymer matrix changes the transport mechanism. Changes in hydrophobicity/hydrophilicity balance of nanocomposite membrane containing metal oxide were reported by Balta et al. They noticed that even ultralow concentration of embedded ZnO nanoparticles (0.035 w/w %) into PES matrix had an important impact on the increasing of membrane hydrophilicity (Balta et al. 2012). Dudek et al. (2012, 2013, 2014) investigated the influence of iron oxide nanoparticles on chitosan and PPO (poly(2,6-dimethyl-1,4-phenylene oxide)) membrane separation properties. In both cases, the addition of magnetite nanoparticles to the polymer matrix has an impact on separation of ethanol/water mixtures. The main important changes in transport properties are observed comparing membranes without and with the iron oxide nanoparticles. The diffusion coefficient increases for one component and decreases for the other with a larger amount of magnetite powder. For the hydrophobic PPO membrane, the component preferentially passing through the membrane is ethanol. It has little tendency to absorb water, so that a droplet remains on the surface. The opposite situation occurs for the hydrophilic membranes. Hydrophilic membranes have an affinity for water. Their surface chemistry allows these materials to be wetted immediately. For such membranes, water preferably passes through the membrane. Comparing the separation properties of both discussed membranes on the basis of permeability coefficients, it can be observed that the poly(2,6-dimethyl-1,4-phenylene oxide) with magnetite addition has better separation properties than the hybrid chitosan membrane. It is demonstrated by the

Iron Oxides: Polymer Composite Membranes, Fig. 1 The comparison of permeability coefficients of water and ethanol for PPO and chitosan membranes

greater difference between the received permeability coefficient for water and ethanol (Fig. 1). The fluxes and diffusion coefficient values also confirm this relation. Large difference between flux and permeation coefficient, for the same amount of magnetite, gives a chance for effective and efficient separation of ethanol/water mixture and gives a chance to concentrate ethanol solution by faster permeation of water from the feed. The reason of bigger difference between the water and ethanol permeability coefficient for hybrid PPO membrane is probably the fact that the iron oxide powder, which is added to the polymer matrix, has hydrophobic properties. The PPO matrix has also hydrophobic properties, so in this case the interaction between polymer matrix and ferroferric oxide particles is very good. The opposite situation is for chitosan membranes with hydrophilic properties. For such membranes, the polymer matrix and iron oxide powder give an opposite effect. As a consequence permeability coefficients for the component preferentially transported through the membrane are not able to reach as high values of transport coefficients as in the case of PPO membrane.

Theoretical Background

The basic law of a phenomenological, parabolic diffusion through a slab membrane of unit cross section is the Fick's law:

$$J = -D(\cdot) \frac{\partial c}{\partial x} \quad (1)$$

where J is the diffusion flux, c stands for the concentration of the diffusing species, and D is diffusion coefficient ($D(\cdot)$ dot stands for the group of variables x, t, c).

When the external force field acts, we rewrite Eq. 1 in the form:

$$J = -D(\cdot) \frac{\partial c}{\partial x} + wc \quad (2)$$

where " w " is a drift coefficient (Strzelewicz and Grzywna 2007).

Crank and Park in (1968) reviewed the more useful experimental techniques for measuring diffusion coefficient. The most fundamental quantity, from many possible, is an average diffusion coefficient $\bar{D}$ calculated from the stationary permeation according to the evident formula, i.e.:

Iron Oxides: Polymer Composite Membranes,

Fig. 2 Schematic view of downstream absorption permeation curve

$$\bar{D}(\text{cm}^2/\text{s}) = \frac{J_s \cdot l}{\Delta c_0} \quad (3)$$

where J_s is a diffusive mass flux in a stationary state, l is the thickness of membrane, and Δc_0 can be obtained from an intercept of the asymptote to the stationary permeation curve with the $Q^a(l, t)$ axis (total flow of penetrant) (see Fig. 2).

Comparing $\bar{D}$ with the value of diffusion coefficient D_L calculated from the downstream absorption time lag (Grzywna and Łuczka 1991; Gadomski et al. 1993; Grzywna 1996; Grzywna and Stolarczyk 2005; Strzelewicz and Grzywna 2007, 2008; Rybak et al. 2009, 2012) (Fig. 2) according to the following equation:

$$D_L(\text{cm}^2/\text{s}) = \frac{l^2}{6L^a(l)} \quad (4)$$

we can get some insight into the nature of the transport process in question, namely, if $\bar{D} = D_L$, the diffusion is supposed to be an “ideal Fickian” unless there are some hidden processes, like a drift, which are beyond the reach of this simple protocol (Grzywna and Łuczka 1991; Gadomski et al. 1993; Grzywna 1996; Grzywna and Stolarczyk 2005; Strzelewicz and Grzywna 2007, 2008; Rybak et al. 2009, 2012). In fact, in the case of the “magnetic membranes,” the presence of a drift is almost certain. To calculate the realistic value of drift and the average diffusion coefficient, we should use a proper theory from which the following formula for time lag $\hat{L}^a(l)$ can be derived (Grzywna and Łuczka 1991;

Gadomski et al. 1993; Grzywna 1996; Grzywna and Stolarczyk 2005; Strzelewicz and Grzywna 2007, 2008; Rybak et al. 2009, 2012).

$$\hat{L}^a(l) = \frac{\bar{D}^2 \left(2 - 2e^{-(w/\bar{D})l} - 2\bar{D}wl + w^2l^2 \right)}{2w^3l} \quad (5)$$

Based on the first Fick's law, we obtain the equation for permeation coefficient determination (Dudek et al. 2013):

$$P = \frac{J_s \cdot l}{\Delta p} \quad (6)$$

where:

P – permeation coefficient [Barrer]

l – membrane thickness [cm]

Δp – difference of gas pressure at both sides of the membrane [cmHg]

J_s – diffusive mass flux [$\text{cm}^3_{\text{STP}}/\text{cm}^2 \cdot \text{s}$]

Diffusive mass flux is defined as:

$$J_s = \frac{Q_{\text{STP}}}{A} \quad (7)$$

where:

Q_{STP} – flow rate at standard condition [$\text{cm}^3_{\text{STP}}/\text{s}$]

A – membrane active area [cm^2]

Flow rate at standard condition is defined as (Dudek et al. 2013):

$$Q_{STP} = Q \cdot \frac{T_{STP} \cdot p}{T \cdot p_{STP}} \quad (8)$$

where:

Q – measured flow rate [cm^3/s]

p – atmospheric pressure [Pa]

T – atmospheric temperature [K]

p_{STP} – standard pressure, $p_{STP} = 1.013 \cdot 10^5$ Pa

T_{STP} – standard temperature, $T_{STP} = 298,15$ K

The solubility coefficient is a measure of the size of the sorption in membranes. It is characterized by division of the penetrant between the membrane and the outer phase in equilibrium. This parameter is calculated from the relation:

$$S = \frac{P}{D} \quad (9)$$

where:

S – solubility coefficient (distribution) $\left[\frac{\text{cm}^3_{STP}}{\text{cm}^3 \cdot \text{cmHg}} \right]$

Ideal selectivity coefficient could be given by quotient of given permeation coefficients:

$$\alpha_{i/j} = \frac{P_i}{P_j} \quad (10)$$

where P_i , P_j is the permeation coefficient of separated components.

Membrane Preparation

Polymer membranes containing iron oxide nanoparticles were prepared using suitable polymer as a matrix, but first of all ferroferric oxide particles were prepared using the precipitation method described elsewhere (Khalafalla and Reimers 1980). For example, 12 g of $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ and 24 g of $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ were each dissolved in 50 ml of water and combined into a 600 ml beaker with addition of 50 ml of concentrated ammonium

hydroxide solution (24 %). The decanted precipitate was washed twice by mixing with a diluted ammonium hydroxide solution (5 ml of ammonium hydroxide in 95 ml of water). After the second washing, the volume of precipitate slurry was adjusted to 50 ml and 4 g of dodecanoic acid (lauric) was added. The next mixture was continuously stirred and heated for 2 min using 550 W laboratory heating plate. Obtained stable magnetite fluid, after filtration in a solid state, was used for preparation of membrane.

Hybrid polymer membranes were prepared by cast method. For this purpose polymer (powder) was dispersed and dissolved in appropriate solvent (Dudek et al. 2012, 2013). After dissolution, the magnetite nanoparticles were added to the polymer solution. For proper dispersion and homogenization of iron oxide particles in the polymer solution, the mixture was sonificated using high-intensity ultrasound radiation. Sonification time was 30 min. After mixing, the solutions were poured into the Petri dishes, placed on the leveled plate, and then evaporated at room temperature for 24 h. In the case of hydrophilicity membranes, the suitable cross-linking agent was applied.

Irreversible Flux Decline

Tony Fane

School of Chemical Engineering, The University of New South Wales, Sydney, NSW, Australia
Singapore Membrane Technology Centre,
Nanyang Technological University, Singapore,
Singapore

Membranes are either operated at constant pressure (P) or constant flux (J); the former is more typical of lab scale studies and the latter of commercial operation. Fouling leads to flux decline under constant pressure or a rise in the required transmembrane pressure ΔP for constant flux. These trends are illustrated in Fig. 1. It should be noted that fouling under constant pressure becomes self-limiting; the lower the flux, the slower the fouling. For constant flux operation, the fouling can be self-accelerating, often leading to a sudden rise in TMP (ΔP) as shown for case (ii) in Fig. 1b. This “TMP jump” could be associated with a critical consolidation of the fouling layer and rapid rise in fouling resistance.

Irreversible Flux Decline, Fig. 1 Constant pressure and constant flux operation: fouling trends

Irreversible flux decline is the drop in flux due to irreversible fouling. The effect of irreversible fouling can also be expressed as irreversible permeability decline (given by the change in $J/\Delta P$), and this can be used for both constant pressure and constant flux operation. However, it is important to note that fouling is flux driven. As a result it is more appropriate to compare membranes at the same initial flux for constant pressure tests. Figure 1a illustrates two membranes, M1 and M2, where M1 has an initially higher permeability and starts at a higher flux. Fluxes for M1 and M2 both decline due to the increasing fouling resistance (see ► [Irreversible Fouling Resistance](#)), and both membranes asymptote to similar declined fluxes. This is due to the eventual dominance of the fouling resistance (R_F) over the membrane resistance (R_m) (see Eqs. 1 and 2 in ► [Irreversible Fouling Resistance](#)). If membranes M1 and M2 were tested at the same constant flux, it would be easier to identify if one was intrinsically less prone to fouling.

Irreversible Fouling

Tony Fane

School of Chemical Engineering, The University of New South Wales, Sydney, NSW, Australia
Singapore Membrane Technology Centre,
Nanyang Technological University, Singapore,
Singapore

Membrane fouling is the accumulation of material on the surface of or within the membrane structure. The foulant may provide a cake or surface deposit layer, and if the membrane is microporous, the foulant could cause pore restriction/closure or pore plugging. These fouling mechanisms are depicted in Fig. 1. Membrane fouling is prevalent in all the liquid-phase membrane processes. Fouling species can be organic macromolecules (proteins, polysaccharides, etc.), inorganics (scale precipitates), and colloidal or biological (biofilms). Fouling is linked to, but different from, concentration polarization (CP). CP is a buildup of retained species (solutes) adjacent to the membrane surface and can be depicted as a boundary layer concentration profile based on a balance between convection (flux driven) and back transport (diffusion). CP increases with flux but is totally reversible when flux is ceased;

Irreversible Fouling, Fig. 1 Membrane fouling mechanisms

fouling is not totally reversible. In many situations fouling has both reversible and irreversible components. The reversible component may be removed by hydrodynamic means, such as back-wash or increased shear at the membrane surface. This type of foulant is usually loosely deposited or bound on the membrane and subject to removal by raised liquid velocities. However, it is not removed by simply dropping flux to zero. The irreversible fouling is material that is tightly held by the membrane. It could be colloids plugging pores, macrosolutes bound by adsorption, insoluble salts spreading as crystals, and biofilms comprising bacteria held in a matrix of extracellular polymeric substances (EPS). Irreversible fouling can usually be mitigated by feed pretreatment, suitable hydrodynamics, and careful membrane selection. For example, pretreatment could remove colloids or bacteria, or involve the addition of antiscalants. Hydrodynamic control could match crossflow velocity to the imposed flux to operate below the critical flux, where the critical flux is the flux below which fouling is negligible. Membrane selection would consider pore size, surface charge, hydrophobicity/hydrophilicity, etc. Irreversible fouling is usually partially removable by cleaning regimes, which could range from daily to monthly, with chemical or physical agents, depending on the situation. However, the gradual buildup of residual irreversible fouling, over multiple cleaning cycles, may eventually reach a critical level, and membrane replacement is required.

For more information on membrane fouling, see “► [Irreversible Flux Decline](#)” and “► [Irreversible Fouling Resistance](#).”

Irreversible Fouling Resistance

Tony Fane

School of Chemical Engineering, The University of New South Wales, Sydney, NSW, Australia
Singapore Membrane Technology Centre,
Nanyang Technological University, Singapore, Singapore

Flux can be related to the driving force ($\Delta P - \Delta \Pi$) and the overall resistance, R_T , by,

$$J = \frac{\Delta P - \Delta \Pi}{\mu(R_T)} \quad (1)$$

The osmotic pressure term ($\Delta \Pi$) can be ignored for non-osmotic operation (i.e., MF applications). The resistance components are assumed to be in series, so,

$$R_T = R_m + R_F \quad (2)$$

where R_m is the membrane resistance and R_F is the fouling resistance, which may comprise a reversible ($R_{r,f}$) and irreversible ($R_{ir,f}$) component, i.e.,

Irreversible Fouling Resistance, Fig. 1 (a)

Concentration polarization – clean membrane. (b) Cake-enhanced concentration polarization – fouled membrane

$$R_F = R_{rr} + R_{ir} \quad (3)$$

For a given ΔP , the flux vs. time data gives the various resistances. The initial clean water flux gives R_m , the final “fouled” flux gives R_T , and $R_T - R_m$ gives R_F . A water flush should remove R_{rr} , leaving resistances $R_m + R_{ir}$. Chemical cleaning should remove R_{ir} , but usually a residual ΔR_{ir} remains as explained in irreversible fouling. For constant flux, the ΔP data can be used to estimate the various resistances.

For processes like reverse osmosis, the osmotic pressure term in Eq. 1 is important. The magnitude of $\Delta \Pi$ is increased in practice by a factor M , the polarization modulus; this is due to concentration polarization. Equation 1 becomes:

$$J = \frac{\Delta P - M \Delta \Pi}{\mu(R_T)} \quad (4)$$

M is the ratio of solute concentration at the membrane surface to the solute in the bulk, and in a well-operated RO desalination process, without fouling, $M = 1.1$ – 1.2 . The polarization modulus, M , can be increased if there is a “cake” layer on the RO membrane surface. The layer provides an unstirred region where the solute (salt) concentration builds up. Figure 1 depicts concentration polarization for a clean and cake fouled RO membrane. The increased polarization (Fig. 1b) is “cake-enhanced” concentration polarization (CECP), and the increased osmotic pressure is the “cake-enhanced” osmotic pressure (CEOP) (Hoek and Elimelech 2003). Both fouling resistance and CEOP contribute to loss of flux (for fixed ΔP) or increased ΔP for fixed flux.

Isotherm Palladium Phase Diagram

Ekain Fernandez
Energy and Environment, TECNALIA,
Donostia-San Sebastian, Gipuzkoa, Spain

Isotherm palladium phase diagram represents the palladium–hydrogen system as a function of pressure, temperature, and H/Pd concentration as shown in Fig. 1.

The isotherm palladium diagram is used to show the nature of one of the biggest problems of pure palladium membranes: hydrogen embrittlement. As shown in Fig. 1, the absorption of hydrogen below its critical point of 571 K (298 °C) and 2 MPa produces two different phases (α and β), both of which retain the pure palladium face-centered cubic (fcc) lattice but with the crystal unit cell lattice parameter increasing from 0.3890 nm for hydrogen-free palladium to 0.3895 nm for the α -phase and up to 0.410 nm

Isotherm Palladium Phase Diagram,

Fig. 1 Pressure–concentration–temperature phase diagram of the palladium–hydrogen system (Lewis 1967)

for the β -phase at room temperature (Lewis 1967; Ohira et al. 1996). The α -phase is obtained at low H/Pd atomic ratios and becomes the dominant phase at high temperature. The β -phase is formed at high H/Pd atomic ratios and coexists with the α -phase at low temperature (Fig. 1). The hydrogen vapor pressure is constant in the region of phase coexistence and is bounded by an envelope defining $\alpha_{\max}$ and $\beta_{\min}$, the compositions of maximum and minimum H/Pd ratio for pure palladium (Yun and Oyama 2011). The change in volume accompanying the phase transformation can give rise to strain and, consequently, after a few cycles to a metal lattice distortion (Shu et al. 1991), and micro-failures inside the metallic bulk are induced.

The alloying of palladium with other metals, lowering the coexistence temperature of the two crystalline phases, reduces the internal strength generated and avoids micro-failure formation inside the alloy bulk. Silver is the most used metal for avoiding hydrogen embrittlement phenomenon in Pd–alloy membranes. The critical temperature for the formation of β -phase of Pd–Ag alloy with a composition of 77 and 23 (%wt) is around room temperature (Paglieri and Way 2002).

Isotope Separation, Membrane for

Grażyna Zakrzewska-Kołodziej
Institute of Nuclear Chemistry and Technology
and Instytut Chemii i Techniki Jądrowej,
Warszawa, Poland

The use of membranes for the separation of isotopes is one of the first practical applications for membrane processes. The first application was based on the effects that were described in 1846

by Thomas Graham, as a phenomenon of molecular effusion, i.e., differentiated flow rate of gases through small holes. When a mixture of two gases in a closed vessel is allowed to permeate through the porous barrier, assuming an equal concentration of the two gases, the molecules of the lighter component strike the barrier more frequently than the molecules of the heavier gas. If the holes of the barrier are sufficiently small to avoid convection flow (flow by volume) of gas and large enough to allow passage of the individual molecules, then the lighter molecules escape more readily through the pores and the permeate is enriched in the light component. The efficiency of partitioning is described by separation factor α expressed as the ratio of mole fractions of separated components after and before passing through the porous barrier or as the square root of the inverse ratio of the corresponding molecular weights:

$$\alpha = \frac{y(1-x)}{x(1-y)} = \sqrt{\frac{M_2}{M_1}}$$

where x and y are mole fractions of two separated isotopes and M_1 and M_2 are molecular weights of these components of the isotopic mixture.

In 1895 Rayleigh and Ramsey have separated argon and nitrogen using this method, and in 1920 Aston employed molecular effusion for enrichment of neon-22 isotope. Large improvement of the technology was achieved by Gustav Ludwig Hertz who developed the separating cascade, which was composed of several diffusion stages. They also used of the 24-stage cascade in 1932, which almost completely separated isotopes of neon, and by applying of the 48-stage cascade, they have separated isotopes of hydrogen. In 1936 Wooldridge, Jenkins, and Smythe have enriched isotopes of neon, hydrogen, and carbon in methane with 34-stage cascade. The most spectacular application of molecular effusion was enrichment of uranium-235 in natural uranium for military purposes within the frames of Manhattan Project during the Second World War. The all of the mentioned processes of separation of isotopes were carried out in the gas phase. In case of uranium isotope separation, the gas applied in

the process was uranium hexafluoride, UF₆. The membrane material had to be chemically resistant in this case, since the uranium hexafluoride used to produce enriched uranium-235 is highly corrosive (easily converted into hydrofluoric acid and harmful oxyfluorides as UO₂F₂). The important parameters of the molecular effusion barrier are the pore diameter and the permeation rate since according to the theory of molecular effusion, the diffusion transport through the membrane is selective when the pore size is commensurate with the mean free path of the molecules under the given conditions.

Also the large plants employing the molecular effusion (which is also called molecular diffusion or gaseous diffusion) were built in the United States with the most famous K-25 plant in Oak Ridge, Tennessee. The other systems were constructed in 1950s at Oak Ridge, Paducah, Kentucky, and Portsmouth, Ohio, in the United States, Capenhurst in England, and at Pierrelatte and Tricastin in France. There are also some reports on gaseous diffusion plants in the former USSR, Great Britain, Argentina, and in the People's Republic of China (Kirk-Othmer 1997). Today, the gaseous diffusion is an important method for uranium-235 enrichment, despite the competitiveness of the centrifugal methods. This is used in the United States and France, including Eurodif, led by France, Italy, Spain, and Belgium, which holds the plants in Tricastin and Pierrelatte (France).

For preparation of membranes, different methods are applied: etching with strong acids (alloys of gold and silver), sintering and extrusion of fine metal powders and oxides of metals (nickel, aluminum oxides), and the anodic oxidation (aluminum oxides). Typical gas diffusion membrane has a pore size of 0.006–0.04 mm and operates at temperature of 60–200 °C and at pressure of 0.4–3.3 bar. Support layer of the membrane is a porous material with a pore size of 2–10 mm. Ceramic and metallic microporous membranes were applied for separation of isotopes, including other than uranium, such as isotopes of argon, neon, and hydrogen. Although information about the materials used for manufacturing gaseous diffusion membranes are very scarce, it is known that French technology

used sintered anode and aluminum, alloys of gold and silver, nickel, Teflon, porcelain (Burggraaf and Cot 1996), and zirconium (Hsieh 1996).

Attempts of using the polymeric membranes for the separation of isotopes of hydrogen with membranes made of polymers, such as polyethylene terephthalate (PET), polyethylene (PE), polytetrafluoroethylene (PTFE), cellulose acetate (CA), and plasticized polyvinyl chloride (PVC), were taken by Marcea (1983). Although the selectivity of polymers is lower than metallic membranes, it is worthy to point out, since the numerous benefits of their use, such as the low-cost of membranes, the possibility of formation of capillaries resulting in large areas for permeation, and no need of high pressures and temperatures.

The studies on separation of hydrogen and oxygen in the liquid phase (water) were carried out in Pacific Northwest Laboratory, USA (Nelson et al. 1996). Polymeric membranes were used in Institute of Nuclear Chemistry and Technology, (Poland). They were made of regenerated cellulose, cellulose acetate (Chmielewski et al. 1991), and polytetrafluoroethylene (Zakrzewska-Trznadel et al. 1996). The economic assessment showed that membrane permeation is competitive with other methods of hydrogen and oxygen isotopes separation. The demand for heavy oxygen water, due to the development of PET diagnostic method, has intensified the interest in new processes of separating isotopes of oxygen, among others – membrane method (Kim et al. 2004).

The following isotopes of chlorine (Campbell 1985), carbon (Fritz et al. 1987), lithium (Whitworth et al. 1994) in aqueous solutions, and uranium (Okamoto et al. 1980) in ammonia were separated by means of various membrane techniques and by using of different membranes. Gadolinium and neodymium isotopes were separated by means of a hybrid complexation/nanofiltration (Chitry et al. 2001) processes. The new complexing agents and ligands, which were

used in the hybrid process, were developed based on DTPA (see also Chitry et al. 2001).

Keggin Structure

Ubavka B. Mioč and Zoran P. Nedić
Faculty of Physical Chemistry, University of
Belgrade, Republic of Serbia

Heteropoly compounds (HPCs) have an almost two centuries-long history. Since 1826, when the first polyoxometalate (POM), $(\text{NH}_4)_3\text{PMo}_{12}\text{O}_{40}$, has been synthesized (Berzelius 1826), they are well known as analytical reagents, catalysts, and biochemical and biomedical active compounds (Rhule et al. 1998; Kuntić et al. 2006). The best known group of POMs are those where heteroatoms are surrounded by a cage of transition metals ($\text{M}=\text{Mo}$ and W), as a result of Mo and W acids polymerization. Two structure types predominate in this group of compounds: Keggin ions $[\text{X}^{n+}\text{M}_{12}\text{O}_{40}]^{(8-n)-}$ synthesized in 1934 (Keggin 1934) and Dawson or Wells-Dawson ions $(\text{X}^{n+})_2\text{M}_{18}\text{O}_{62}^{(16-2n)-}$, with structure determined in 1953 (Pope 1983) (Fig. 1). It is evident from Fig. 1a how Keggin anion is formed. On each corner of central tetrahedron, three WO_6 octahedra are bonded sharing corners and sides. Thus, such group could be presented as an M_3O_{13} group. It is possible to distinguish four oxygen atoms in such structure: O_1 (terminal), O_2 (edge bridging), O_3 (corner bridging), and O_4 atoms shared with central tetrahedron. Typically,

heteroatoms are phosphorus (P) and silicon (Si); nevertheless, some other metals such as V , Nb , Ta , and U also show comparable behavior, but to a more limited extent. Bands in IR and Raman spectra, characteristic for host lattice, and used for quick and ease identification of POMs, are assigned to PO_4^{3-} group (at about 1,003, 988, and 983) $-\nu_1$ stretching and at 516 cm^{-1} are assigned to PO_4^{3-} asymmetric bending vibrations. Some other bends are assigned to groups of addenda atoms: about 805 to $\text{W}-\text{O}-\text{W}$ asymmetric stretching, at 536 to $\text{W}-\text{O}-\text{W}$ symmetric stretching, and 273 cm^{-1} $\text{W}-\text{O}-\text{W}$ bending vibrations. Below 450 cm^{-1} lattice modes are expected (Rocchiccioli-Deltcheff et al. 1983; Mioč et al. 1994). Keggin anions form channels full with water and hydrated protons (cf. “Heteropoly Acids”).

POMs of Mo and W are of two types, isopolyoxometalate and heteropolyoxometalate, which contain one or two atoms of another element (heteroatom) besides molybdenum or tungsten, oxygen, and hydrogen. More than 65 elements from all groups of the periodic table can be found incorporated into polyoxoanions as heteroatom. Covalent attachment of amino acids as glycine, alanine, and lysine to POMs is also possible. Such compounds are interesting especially for the investigation of biochemical and biomedical activity of HPCs (Rhule et al. 1998; Kuntić et al. 2006).

Keggin Structure, Fig. 1 Three predominate structure of POMs: (a) group of three WO_6 octahedra around central PO_4 tetrahedron of Keggin anion; (b) primary structure of Keggin anion; (c) Dawson's structure

After the discovery of their superionic proton conductivity ($\sigma = (1\text{--}100) \times 10^{-3}$ S/cm) at room temperature in 1979 by Nakamura et al. (1979, 1981), the chemical and electrochemical conductive properties of these selected compounds have become very interesting as new materials, potentially useful for different solid-state devices: as sensors, proton exchange membranes (PEM) in H_2/O_2 fuel cells, electrochromic displays, and ion-selective membranes (Colomban 1992). Proton conductivity (not lower than 1×10^{-4} S/cm) is necessary to enable the use POMs as PEM in fuel cells, or in batteries (Mioč et al. 2005; Holclajtner-Antunović et al. 2010; Mentus et al. 2010). But regrettably they also have some deficiencies. They are sensitive to ambient conditions: relative humidity (RH) and temperature. Also, they have low specific surface area ($20\text{--}30$ m^2/g) and are washable from PEM. These deficiencies may be avoided if HPCs are incorporated in composites, and/or polymers, and also if POMs are used as acid insoluble salts of heteropoly acids, or some other compounds, as bronzes, where HPCs have been used as precursors (Mentus et al. 2010).

The applications of POMs are associated with their size, high ionic weight and redox characteristics, polarity, surface charge distribution, electron and proton transfer/storage ability, the formation of high Brønsted acid centers, and so on.

Kinetic Study in Bulk Liquid Membranes

Gerardo León

Departamento de Ingeniería Química y Ambiental, Universidad Politécnica de Cartagena, Cartagena, Spain

Kinetic study of the transport of different chemical species through bulk liquid membranes has been widely studied, including metallic ions (Cu^{+2} , Co^{+2} , Cr^{+6} , Hg^{+2} , Na^+ , Pd^{+2} , U^{+6}), anionic species (CN^- , SCN^- , Cl^-), dyes (methylene blue, cibacron red FN-R), amino acids (valine, phenylalanine), and other compounds. Most of these studies have employed carrier-mediated transport

mechanisms by using different types of carriers and organic diluents in the membrane phase and different stripping agents in the product phase. Dimensionless reduced concentrations of the target species in the feed (R_f), membrane (R_m), and product phases (R_p) were used ($R_f = C_{ft}/C_0$; $R_m = C_{mt}/C_0$; $R_p = C_{pt}/C_0$; the sum $R_f + R_m + R_p$ obviously being unity).

In most of these studies, the variation with time of the reduced concentrations of target species decreased monoexponentially in the feed phase, followed an increasing sigmoided-type curve in the product phase and presented a maximum in the membrane phase (Fig. 1).

All these results suggest that target species transport through bulk liquid membranes by using a carrier mediated transport obeys the kinetic laws of two consecutive irreversible first-order reactions, i.e., the extraction (rate constant, k_{ex}) and the stripping (rate constant, k_{st}) reactions (Szpakowska and Nagy 1991; He et al. 2000; León and Guzmán 2005). The irreversibility is to be expected because R_f and R_m tend to be zero, while R_p tends to be one, that is, the transport from the feed phase to the product phase seems to be virtually complete. This kinetic behavior can be mathematically described according to the following equations:

$$\frac{dR_f}{dt} = -k_{ex}R_f \equiv J_{f/m} \quad \frac{dR_m}{dt} = k_{ex}R_f - k_{st}R_m$$

$$\frac{dR_p}{dt} = k_{st}R_m \equiv J_{m/p}$$

Kinetic Study in Bulk Liquid Membranes,

Fig. 1 Typical curves of time dependence of R_f in feed phase, R_m in membrane phase, and R_p in the product phase, in the transport of a chemical specie through a bulk liquid membrane by using a carrier facilitated transport

Integration of those differential equations gives $R_f = \exp(-k_{ex} t)$

$$R_m = \frac{k_{ex}}{k_{st} - k_{ex}} [\exp(-k_{ex} t) - \exp(-k_{st} t)]$$

$$R_p = 1 - \frac{1}{k_{st} - k_{ex}} [k_{st} \exp(-k_{ex} t) - k_{ex} \exp(-k_{st} t)]$$

These equations show that the time dependence of R_f is monoexponential and the time dependence of both R_m and R_p is biexponential.

R_m has a maximum $R_m^{\max} = \left(\frac{k_{ex}}{k_{st}}\right)^{-\frac{k_{st}}{k_{ex}-k_{st}}}$ at time $t_{\max} = \frac{\ln\left(\frac{k_{ex}}{k_{st}}\right)}{k_{ex}-k_{st}}$

Maximum fluxes can also be obtained:

$$\left[\frac{dR_f}{dt}\right]_{\max} = -k_{ex} \left(\frac{k_{ex}}{k_{st}}\right)^{-\frac{k_{st}}{k_{ex}-k_{st}}} = J_f^{\max}$$

$$\left[\frac{dR_m}{dt}\right]_{\max} = 0$$

$$\left[\frac{dR_p}{dt}\right]_{\max} = k_{st} \left(\frac{k_{ex}}{k_{st}}\right)^{-\frac{k_{st}}{k_{ex}-k_{st}}} = J_p^{\max}$$

$$-\left[\frac{dR_f}{dt}\right]_{\max} = +\left[\frac{dR_p}{dt}\right]_{\max} \Rightarrow -J_f^{\max} = +J_p^{\max}$$

Moreover, in many cases, the activation energy values of the processes were obtained from the Arrhenius equation, $\ln k = \ln A - \frac{E_a}{R \cdot T}$, by using the k_{ex} and k_{st} values at different temperatures.

Notwithstanding the previous comments, kinetic studies on Cu(II) transport through bulk liquid membrane containing 2-hydroxy-5-nonyl-benzaldehyde (Acorga P-50) as carrier in *n*-octane and sulphuric acid as stripping agent (Szpakowska and Nagy 2000) described that the $[Cu(II)]/[Carrier]$ ratio influences the kinetic regime. It was found in these studies that for $[Cu(II)]/[Carrier]$ ratio higher than 5, both the extraction and the stripping steps were of zeroth order with respect to copper, with remaining copper concentration in the membrane small and practically constant. When $[Cu(II)]/[Carrier]$

ratio was lower than 1, the process followed the kinetic laws of two consecutive irreversible first-order reactions, with reduced concentrations of Cu(II) decreasing monoexponentially in the feed phase, following an increasing sigmoided-type curve in the product phase and presenting a maximum in the membrane phase. Between these two ratio ranges, the kinetics was of intermediate character. These results show the possibility of changing the transport kinetics by varying the $[Target\ species]/[Carrier]$ ratio.

Knudsen Diffusion

Renzo Di Felice

University of Genova, Genova, Italy

Synonyms

[Knudsen transport modeling](#)

Whenever a species is diffusing inside a confined space, such as cylindrical pore, an interaction between the diffusive molecules and the pore

wall is to be expected. One possibility is given by the pore wall physically interacting with the diffusive molecules and hindering, as a consequence, their movement. The phenomenon, called Knudsen diffusion, is relevant whenever the distance between molecular collisions is greater than the pore diameter. This interaction can be the governing factor of the diffusion rates.

Liquid have a relatively small mean-free path, few angstroms, so that Knudsen diffusion is not important in practical cases, but on the other hand, for gas this parameter can assume values larger than 1,000 Å and therefore be significant.

The diffusion coefficient, D_{Kn} , in the Knudsen regime can be estimated from gas kinetic theory, and it is given by

$$D_{Kn} = 4850d\sqrt{\frac{T}{M}}$$

where d is the pore diameter in cm, T the absolute temperature, and M the molecular weight of the diffusive species. Unlike diffusion in unbounded systems, Knudsen diffusion coefficient is independent of pressure and of the molecular weight of the second species.

Lamellar Copolymers

Mario Malinconico
Research Director, Institute for Polymers,
Composites and Biomaterials (IPCB-CNR),
Pozzuoli, Naples, Italy

The presence of covalent bonds between the blocks in block copolymers leads to severe restrictions on the state of local segregation between them allowing the formation of few and defined morphologies. Comparing the phase separation that occurs in a pure copolymer AB and into the corresponding mixture of homopolymers HA/HB and assuming that in both cases strips of different phases are formed, parallel to the surface of the system, it is observed that in the mixture the size of the homopolymeric lamellae parallel to the surface and perpendicular to it are both much greater than the radius of gyration (R_g) of the polymer. Instead, in the case of the block copolymer, the presence of the bond between the blocks allows the formation of lamellae whose dimensions parallel to the surface are much greater than the radius of gyration, but the size perpendicular to the surface has dimensions comparable to the radius of gyration. On the basis of this different structural feature, the domains of different compositions which are formed in a mixture of homopolymers are named macrophases, while in the case of a copolymer are spoken of microphases or even, sometimes, of nanophases (Fig. 1).

There are numerous methods for inducing the orientation and order of large-scale morphologies of the copolymers blocks, such as lamellae. Some main strategies used are reported:

- Fields of mechanical flow (extrusion (Keller et al. 1970; Folkes et al. 1973), compression (Kofinas and Cohen 1995; Drzal et al. 2001; Quiram et al. 1998; van Asselen et al. 2004), flows involving oscillating (Skoulios 1977; Hadziioannou et al. 1979, p. 15, 1979, p. 136; Morrison and Winter 1989; Morrison et al. 1990; Wiesner 1997; Scott Pinheiro and Winey 1998; Leist et al. 1999; Hermel et al. 2002; Stangler and Abetz 2003; Wu et al. 2004) or stationary (Sebastian et al. 2002; Angelescu et al. 2004, 2005; Luo and Yang 2004) shear, or techniques that combine different flow fields (Albalak and Thomas 1993, 1994; Honeker et al. 2000; Dair et al. 2000; Villar et al. 2002)) were successfully used to induce alignment in block copolymers.
- Magnetic fields induce orientation in liquid crystalline block copolymers (Osuji et al. 2004; Tomikawa et al. 2005) and block copolymers with a crystallizable block through an accurate control of the crystallization process (Grigorova et al. 2005).
- Static electric fields have been widely used to guide macroscopically cylindrical and lamellar morphologies in the melt of such copolymers (Morkved et al. 1996; Onuki and Fukuda 1995;

Lamellar Copolymers,

Fig. 1 Phase separation in block copolymers (a) and in homopolymers blend (b) (Schulz and Bates 1996)

Thurn-Albrecht et al. 2000, 2002; Elhadj et al. 2003; Xu et al. 2004; DeRouchey et al. 2004; Xiang et al. 2004).

- Solvent evaporation allows the orientation of lamellar microdomains perpendicularly to the film surface (Turturro et al. 1995; Kim and Libera 1998, p. 2569, 1998, p. 2670). After the deposition, the glass transition temperature (T_g) of the film swollen with a solvent is below the ambient temperature, allowing free mobility of the chains. With increasing concentration of the solvent, the copolymer undergoes a transition from the disordered state to the ordered. The diffusion of the solvent in the thin film produces a concentration gradient so that

order spreads rapidly from the surface of the film to the substrate. The consequent decrease of T_g below room temperature, for at least one block, freezes the structures that, due to the high directionality of the solvent gradient, organize into domains with lamellar axes perpendicular to the surface (Kim et al. 2004; Kimura et al. 2003; Lin et al. 2002; Temple et al. 2003).

A great potential of the block copolymers is represented by the possibility of using the ordered nanostructures formed by self-assembly as a matrix (host) for the inclusion of guest molecules (guest) and dispersion of different types of

Lamellar Copolymers,

Fig. 2 Bright-field TEM image of a thin film of a lamellar block copolymer polystyrene-poly(ethylene-co-propylene) in which gold nanoparticles suitably passivated are included only in the layers of polystyrene (Bockstaller et al. 2005)

nanoparticles, in order to obtain nanocomposites with special physical properties. The nanocomposites represent a class of composite materials consisting of matrix and a polymeric particle reinforcement having at least one dimension of the order of nano; such particle reinforcements are called nanofillers or nanoreinforcement.

The different microdomain nanostructures generated by block copolymers (lamellae in particular, but also spheres or cylinders) act as host to sequester selectively nanofillers (guest) with a suitable chemical and geometrical affinity.

The great innovation of these studies consists in the fact that the use as a matrix of block copolymers, then nanostructured materials already, instead of homopolymers, offers an important opportunity to control the distribution of spatial and orientational nanofillers. The nanoparticles, which induce specific properties, are not, in fact, randomly distributed in the polymer matrix but are sequestered in ordered microdomains and, thus, distributed in an orderly manner in the matrix. This allows a greater control of the final physical properties of the nanocomposites. A TEM image of a thin film of a nanocomposite based on a lamellar block copolymer in which gold nanoparticles are distributed in such an ordered way only in specific layers of the structure is shown in Fig. 2 (Bockstaller et al. 2005).

Langerhans Islet

Loredana De Bartolo and Antonietta Messina
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The **islets of Langerhans** are endocrine cell cluster well ordered in lobules, of 0.3–0.7 mm in diameter, containing from 3,000 to 4,000 cells, and located mainly in the tail region of the pancreatic gland. Discovered in 1869, though representing only 2 % of the whole organ, they serve to coordinate the physiological control of the glycemic values in the blood. Five different hormone-secreting cell types constitute the islets' cytoarchitecture: alpha cells producing glucagon, beta cells producing insulin and amylin, delta cells producing somatostatin, PP cells (gamma cells) producing the pancreatic polypeptide, and epsilon cells producing ghrelin. In human beings, the alpha and beta cells are in close relationship with each other. Representing nearly 90 % of the total islet cells, their secretive activity is modulated by the blood glucose levels: when low concentrations of sugar are detected, the islets respond with the glucagon secretion to induce the glucose release from the hepatic deposits into the bloodstream. After a meal the high concentration of the blood sugars causes the beta cell activation determining the insulin-induced glucose metabolism and the production of the energy requested by the body. Since the interaction between the hormone-secreting cells of the islets and the paracrine, electric, and nervous-regulating factors is highly complex, the tiniest decompensation in the islet cells' functions, modulation, and survival can result in the onset of severe pathologies and organic disorders, which leads patients to severe complications and a high risk of death. Actually, 98 % of the diseases involving the pancreas referred to the loss of the ability in modulating the food sugars' conversion into energy, due to the malfunctioning or destruction of the

insulin-producing beta cells by autoimmune responses. Thus, sustaining and/or replacing malfunctioning islets is the only therapeutic approach in order to induce the partial recovery of the metabolic functions in the patients (Patel et al. 2014). Before 1893 and the discovery of the pancreas involved in the income of the diabetes, starving was the only treatment possible for people suffering for diabetes. Then, first attempts in the development of grafts were made using deceased donor's islets serving as substitutes for the malfunctioning pancreas. Many patients showed a partial recovery; however, after transplantation, these islet grafts were inevitably destroyed due to the immune and inflammatory reaction in the hosts. In truth, despite the risk/benefit trade being quite high for the patients, *the transplantation* still remains the only therapeutically approved approach to gain the patients recovery of the pancreatic activity. Allo and autotransplantation are nowadays performed through the infusion of purified islets into the portal vein of the liver, and 50 % of the receivers are able to regain the pancreatic functionality and recover from the systemic complications in 1 year. However, the number of available and compatible donors is quite limited, and the lifetime immunosuppression therapy exposes the patient to infections, diseases, and harmful side effects. Thus, new techniques labeled as tissue engineering approaches have been developed to overcome these disadvantages and foresee the use of polymeric membrane systems to produce engineered device containing islets of insulin-producing cells, to control the release of the cell products from the islets, their sustainment, and their protection from the immunoreactive species in the site of implantation. Coordinated by local drug delivery systems, consisting in bores of low-dose anti-rejection drugs able to minimize the immune response as well as any inflammatory effects at the site of implantation, the *encapsulation* technique is the most promising method. The islets are wrapped in a tight coating made of biocompatible polymers acting as a perm-selectivity membrane that serves to mimic the heterogeneous and safe

environment where oxygen and nutrient perfusion is provided continuously and appropriate space and ECM-like physical and mechanical support, essential for the correct insulin production and secretion and the islets' survival, are provided. Different classes of encapsulating devices are available and classified depending on their size in macro-, micro-, and nano-devices. Classified as extravascular diffusion devices when placed subcutaneously or in the peritoneal cavity and intravascular diffusion system, three *macrodevices* have been approved for the clinical trials: *the TheraCyte system*, made up of two composite Teflon-based membranes in between the islets are placed; *the Islet Sheet device*, constituted by supported alginate sheets containing the pancreatic islets; and *the Beta O₂ device* able to increase the oxygen exchange in the implantation site being made of oxygen-generating biomaterial able to deliver locally the oxygen to the cells. Additional macrodevices consist of tubular porous membranes filled with islets generally placed into the vessels, where adequate kinetic properties allowed the insulin release straight into the blood stream. *Micro devices* constituted by single cluster of beta cells incorporate into semipermeable polymeric membranes, and *nano-devices* are nowadays under investigation in a few animal models. They differ generally on the processing methods used for the encapsulation of the islets and both allow to increase the insulin release rate and the oxygen exchange into the islets. The micro systems are processed in a spherical system of alginate hydrogels coated with poly-ornithine and polylysine or by cross-linking a thin hydrogel sheet onto an islet cluster by the *conformal coating* methods, whereas the nano-devices (1–100 µm) consist of islets encapsulated by alternating charged polylysine, polyglutamic acid, and PEG-biotin polymers over the cell aggregate surface through the *layer-by-layer method*. The decreased thickness of the capsules obtained by covering the islets with a single sheet of molecules increases and improves the insulin release kinetics after implantation and resulting as well in higher diffusion of nutrients in the core of the cell clusters. Independently on the size of the device, three different encapsulated

replacement strategies are available for the implantation: All-In/Biodegrade-Out replacement, made of biodegradable components easily absorbed by the body; All-In/All-Out replacement, designed to not react with the host tissues as the cytotherapeutics devices, the islet sheet medical devices, and the beta-O₂ device; and Flush/Reload replacement used for the macrodevices designed in order to grow into the host to provide a vascular interface (David and Marchetti 2014). *New cell sources*. To overcome the shortage of donor organs and the side effect linked to the autoimmune destruction of the patient islets as for diabetes type I, alternative sources of beta cells have been researched. The adult stem cells or progenitor cells appear to be the most promising. Through reprogramming cell strategy (transdifferentiation), pancreatic precursor cells are reprogrammed in insulin-producing cells. Moreover, the own patients pancreas exocrine cells and the skin cells that can undergo to the reprogramming technique representing a promising new source for the beta cells supply, being not needed the immunosuppression therapy after the implant (Dominguez-Bendala et al. 2013). Therefore, another potential source of beta cells may be the xenotransplantation with pig pancreas cells. Interestingly, human and porcine insulin differ only for one amino acid, and insulin extracted from porcine pancreas has been used for the treatment of patients with diabetes before the development of recombinant human insulin technology. However, several problems need to be overcome for porcine islet transplantation to become a viable clinical option; however, studies in rodents and large animals have shown great promise that justifies cautious optimism for the near future. In the last years, another chance to improve the tissue engineering of the pancreas appears to be the prevention of the inflammation at the site of the transplant, co-transplanting mesenchymal stem cells. The MSCs that have been demonstrated offer natural defenses by blocking the signals of the immune responses, limiting inflammation, stimulating the blood vessel growth, and promoting the long-term function of islets due to their trophic effects.

Up until now, though the most important progress in the pancreatic islet transplantation is

settled in preclinical trials and only one lead research project has been presented in the last years on baboons, 95 % of the patients who received the capsule implantation resulted in considerable improvements of the glucose metabolism with the reverse of the main diabetes side effects at 1 year and more than 80 % at 5 years after implants opening new hopes in the further improvement of new strategies for the diabetes treatment in the nearest future.

Langmuir and Langmuir–Blodgett (LB) Films

Osvaldo N. Oliveira Jr and Diogo Volpati
Sao Carlos Institute of Physics – IFSC, University of Sao Paulo – USP, Sao Paulo, Brazil

An ultrathin, resistant layer can be formed at the air-water interface by spreading a single drop of oil. This phenomenon was discovered centuries ago, but it was *Irving Langmuir* that in the early twentieth century established sound theoretical and experimental basis for their study (Langmuir 1917). The now-called Langmuir monolayers are formed at air-water interfaces using an experimental system known as Langmuir trough. Basically a solution containing amphiphilic molecules

(with both hydrophobic and hydrophilic parts) is spread over at the air-water interface. The hydrophilic parts allow the spreading of the molecules while the hydrophobic parts do not let the molecules dissolve into subphase. Movable barriers are used to compress the monolayer. The presence of the monolayer can be detected easily by measuring the surface pressure (π), which is the decrease in surface tension, as the monolayer is compressed, thus leading to pressure-area isotherms.

In the 1930s, *Katharine Blodgett* – then an assistant to *Langmuir* – developed the procedures to transfer the monolayer onto a solid substrate (Blodgett and Langmuir 1937). The deposited films are now termed Langmuir-Blodgett films. Basically, monolayers can be transferred by immersing (or withdrawing) the substrate into (or from) the liquid while the monolayer is adsorbed homogeneously at the substrate. Thus, well-ordered films with very accurate thickness can be formed.

Layer-by-Layer (LbL) Method

Saren Qi¹ and Chuyang Y. Tang²

¹Singapore Membrane Technology Centre, Nanyang Technological University, Singapore, Singapore

²Department of Civil Engineering, The University of Hong Kong, Hong Kong, Hong Kong SAR

Layer-by-layer (LbL) method (also known as LbL assembly, electrostatic self-assembly (ESA), or polyelectrolyte multilayer (PEM) technology) is

Layer-by-Layer (LbL) Method,

Fig. 1 Simplified schematic of the film deposition process using LbL method

a versatile method to form multilayers on a solid support. The self-assembly method is driven by the electrostatic force between the precursor materials. Precursor materials to form multilayers can be chosen from polyelectrolytes, biopolymers, clays, metal complex and their derivatives, nanoparticles, dendrimers, and so on (Bertrand et al. 2000). The advantages of this method are the relatively simple process, independence of substrate properties (i.e., size, topology, materials, and so on), and formation of fuzzy structure. Therefore, LbL method has a potential to be applied in various applications including forming multicomposite films, nanoparticle modification, enzyme process, optic development, sensors, membrane for water treatment, fuel cell, and so on.

The basic formation mechanism of a typical LbL process is shown in the schematic drawing in Fig. 1. Step (1) shows the absorption of polycation by a negatively charged substrate. After washing with deionized water (step (2)), the substrate was soaked in a polyanion solution (step (3)). Then, it is washed with deionized water (step (4)). These procedures can be repeated to prepare multilayers on the substrate. Other variations to this basic coating method includes spray (Schlenoff et al. 2000), spin (Chiarelli et al. 2001), hydrodynamic LbL deposition (Deng et al. 2008), electric field-induced LbL process (Zhang

et al. 2008), and pressure-induced LbL process (Zhang et al. 2011). Characteristics of the LbL films are known to be highly affected by the preparation procedures and conditions. In addition to the substrate and multilayer materials, other main factors affecting LbL film properties include ionic strength of coating solution, solution pH, coating time, and the use of cross-linkers.

Layer-by-Layer Self-Assembly Membrane

Emma Piacentini and Lidietta Giorno
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Layer-by-layer (LbL) self-assembly membranes are multilayered nanoarchitectures obtained by depositing oppositely charged polyelectrolytes or molecules presenting mutually interacting binding sites (Table 1) (Borges and Mano 2014). The LbL method can not only be applied to polymers but also on the combinations of polymers with particles.

The LBL assembly based on electrostatic interaction is the most used and investigated method for multilayered nanoarchitecture construction. In this case, LbL self-assembly membranes are produced by simply repeating the alternate immersion of a charged substrate in the corresponding polyionic solution of opposite charge (Fig. 1). To speed up the deposition process, otherwise time consuming as a consequence of the necessity to wait several minutes between each step of adsorption and rinsing, spray deposition and spin coating have been demonstrated to be suitable. The method is very attractive due to its simplicity and efficiency in film preparation; however, the multilayer assemblies are less stable and robust than the ones obtained by hydrogen or covalent bonding.

The LBL growth, structure, and properties of multilayer assemblies are influenced by several physicochemical parameters such as pH, ionic strength and electrolyte species, temperature, solvent quality, adsorption time, and the intrinsic properties of polyelectrolytes such as charge density, concentration, architecture, and molecular weight.

Despite the several methods available for LBL assembly of multilayer films, the concept of LBL assembly based on multiple intermolecular interactions opens for a great variety of materials with well-defined properties in terms of thickness, compositions, structure, wettability, building, or charged/uncharged for a wide range of applications.

Potential applications of LbL membranes are in biomedical field such as drug delivery, gene transfection, and biosensors (Yoon et al. 2014). The controlled drug delivery can be achieved using hydrolytically degradable polymers such as poly (β -amino ester). Gene transfection is obtained by using plasmid DNA as an anionic layer to form LbL films. Biosensors can be produced by using charged biomolecules such as glucose oxidase (able to catalyze glucose oxidation with simultaneous production of hydrogen peroxide) used as glucose sensor. LbL membranes can also be used in tissue engineering by introducing functional groups onto the surface of LbL membrane able to promote cell proliferation and differentiation as substrate or by using cells as a template of LbL systems.

The LbL self-assembly technique has been explored in the development of electrochemical energy conversion and storage devices from fuel cells to supercapacitors (Xiang et al. 2012). Other recent applications include water treatment like water softening, desalination, and recovery of certain ions (Sanyal and Lee 2014). Advantages of LbL self-assembly technology include

- Its simplicity and low cost
- Variability of the applicable materials (conventional polyelectrolytes, water-soluble

Layer-by-Layer Self-Assembly Membrane, Table 1 Materials available for Layer-by-layer (LbL) self-assembly membranes

Molecules	Attractive Force Type	Examples
Polyelectrolyte polymers	Electrostatic interaction	Poly(styrenesulfonate) (PSS) Poly(allylamine hydrochloride) (PAH) Poly(L-lysine)/alginate (PLL/ALG) PLL/hyaluronan (PLL/HA) PLL/poly(L-glutamic acid) (PLL/PGA), PLL/poly(acrylic acid) (PLL/PAA), PGA/PAH, chitosan/HA (CHT/HA), poly(ethylenimine)/PAA (PEI/PAA)
Polymers carrying hydrogen donor and acceptor moieties	Hydrogen bonding	Poly(vinylpyrrolidone) (PVP) Poly(vinyl alcohol) (PVA) Poly(acrylamide) (PAA) Poly(ethylene oxide) (PEO) Poly(vinylpyrrolidone) (PVPON) Poly(methacrylic acid), PMAA
Uncharged molecules	Hydrophobic interactions	Alkanethiols-proteins
Molecules having complementary functional groups	Covalent bonding	Poly(vinylamine-co- <i>N</i> -vinylisobutyramide) [Poly(VAm-co-NVIBA)] and PAA. Carboxyl group of PAA activated by 1-ethyl-3-(3-(dimethylamino)propyl)-Carbodiimide hydrochloride (EDC) and amine groups of poly(vinylamine-co- <i>N</i> -vinylisobutyramide) Poly(VAm-co-NVIBA)
Stereoregular polymers carrying sites of opposite chirality	Stereocomplexation	(It-st)poly(methyl methacrylate) (PMMA)
Host (e.g., cyclodextrins, cucurbiturils, calixarenes, pillararenes, crown ethers, porphyrins) and guest (e.g., ferrocene, adamantane, azobenzene) molecules.	Host-guest interactions	Cyclodextrin (β -CD) and adamantane
Nonionic molecules, which present electron-accepting and electron-donating groups, respectively, in the side chains.	Charge-transfer interaction	Y[2-(9-carbazoyl)ethyl methacrylate] (PCzEMA, electron-donor polymer) and poly[2-[(3,5-dinitrobenzoyl)oxy]ethyl methacrylate] (PDNBMA, electron-acceptor polymer)
Avidin and biotin-labeled polymers or Antibody – Antigen conjugated molecules or lectin – carbohydrate or DNA hybridization	Biologically specific interaction	Biotin – protein conjugate and polymerized streptavidin on hydrophobic silica surfaces
Metal ions and organic ligand	Coordination chemistry interactions	Poly(copper styrene 4-sulfonate) (PSS(Cu) _{1/2}), and PVP

- proteins, charged polysaccharides, as well as charged inorganic substances, including colloidal nanoparticles, heteropolyacids, and metal nanoparticles)
- Precise microstructural control and high repeatability
- Great control over the composition of the film along the vertical direction by changing the nature of the building blocks that are deposited during each step
- Extensive possibility in wide range applications
- Its nontoxic and environment-friendly nature

Leather Industry

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In the **leather industry**, the animal rawhide is converted into finished leather, a durable and

flexible material, through a series of chemical and mechanical treatments.

The steps in the production of leather between curing (a salt treatment to prevent putrefaction of the collagen) and tanning (a treatment of leather stabilization with vegetable or mineral substances) are collectively referred to as *beamhouse operations*. They include, in order, soaking, unhairing/liming, deliming/bating, and pickling. All these processes are realized in chemical reactors (tumblers) in which the skins react with different chemicals (acids, alkalis, chromium salts, tannins, solvents, sulfides, dyes, auxiliaries, etc.) in aqueous solutions (Fig. 1).

Wastewaters coming from different tanning operations contain high concentrations of organic and inorganic substances causing significant pollution phenomena. Organic pollutants come from the skins (it is calculated that the raw skin has 30 % loss of organic material during the working cycle), or they are introduced during the working cycle (e.g., tanning). Inorganic pollutants are a residual of the used chemicals (i.e., chromium salts) that are not completely fixed by the skins owing to the low efficiency of the operations (Cassano et al. 2001).

Leather Industry, Degreasing

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In the degreasing step, fats and grease are removed from the interfibrillary spaces with the use of lipases, detergents, or solvents in order to

allow the penetration of various tanning materials and dyes. This operation is necessary especially for sheepskins where the percentage of fat substances on raw weight is of about 30–40 %.

Enzymatic degreasing is a better way of carrying out degreasing than the use of solvents and detergents. Lipases are much safer and less toxic to workers and the environment.

Ultrafiltration (UF) can be used to treat the exhausted bath from the degreasing operation in order to recover surfactants in the permeate stream which can be recycled to the degreasing step leading to a reduction in raw material costs. Fat substances removed from the skins can be concentrated in the retentate stream and reused, after physical and chemical treatments, in the fat liquoring step with significant reduction of the wastewater treatment costs (Koltuniewicz 2010).

In another approach the UF process can be combined to an enzymatic degreasing step (Fig. 1) with a continuous recycling of the permeate stream in the drum (Cassano et al. 1998).

The proposed methodology permits to obtain a high removal efficiency of fatty substances from the degreasing bath and a reduction of washing cycles normally employed to remove the lipidic substances from skins and, consequently, of water consumption. Polysulfone membranes with molecular weight cutoff of 20 kDa, in spiral-wound configuration, exhibited rejections toward chemical oxygen demand (COD) and fat substances higher than 97 %.

Leather Industry, Soaking

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In this operation, raw skins are exposed to water and chemicals (small quantities of imbibing substances) in order to hydrate proteins and fibers, to solubilize the denatured proteins, and to eliminate

salt compounds with dirt (blood, excrement, earth) which are attached to the skins.

The soaking-exhausted effluent-containing excrements, salts, and chemical additives are normally discharged into a water-treatment plant (Sharphouse 1983).

UF membranes can be used to concentrate organic components in the feed tank of the UF plant. A clear permeate, enriched in salt compounds, could be reused in the pickling step after adjustment of the salt concentration with NaCl (Fig. 1). Preliminary treatments are necessary in order to remove the suspended materials; a sedimentation step allows to reduce the suspended solids of 90 %; then steel spring filters (200–300 μm net size) could be employed to remove large particles avoiding clogging phenomena of UF membranes (Cassano et al. 2001).

Leather Industry, Unhairing-Liming

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The aim of the unhairing-liming step is to remove from the raw skin all the components which are

Leather Industry, Soaking,

Fig. 1 Treatment of exhausted effluents of the soaking step by UF process

Leather Industry, Unhairing-Liming, Fig. 1 Treatment of exhausted liming effluent by ultrafiltration

not transformed into leather, such as the superficial epidermis including the hair and the subcutaneous adipose layer. The liming step introduces chemicals such as lime (Ca(OH)_2) and sodium sulfide (Na_2S) or sodium hydrosulfide (NaHS) which open the fibrous structure of the skin. Consequently, exhausted effluents are highly polluted for the presence of sulfide, amines, organic matter coming from degradation of hairs and epidermis, and high concentration of alkalis. The COD of exhausted effluents ranges between 20,000 and 40,000 mg/L of consumed oxygen.

The UF treatment of the exhausted unhairing liquor has been one of the first membrane approaches introduced in the leather industry (Molinari 1995). It can be exploited to recover sulfide and solubilized lime together with low molecular weight proteic substances in the permeate stream in order to reuse the purified solution for the preparation of a new liming bath. High molecular weight proteic components, coming from chemical degradation of hairs and epidermis, are concentrated in the retentate stream (Fig. 1).

Considering that 60–65 % of the initial sulfide remains in the exhausted liquor and 5–10 % is lost in the retentate, the quantity of sulfide that is possible to recycle with an UF system is 55–60 %.

An innovating system based on the use of enzymes and small quantities of sodium sulfide (1.5 % instead of 10 %) has been proposed and tested on industrial scale. In this approach the enzymatic unhairing was combined to the continuous cross-flow UF of the bath permitting to keep constant the sulfide concentration in the unhairing bath due to its permeation through the UF membrane. The organic components (products of degradation of the keratin and of the interfibrillar proteins, fat substances, etc.) are concentrated in the retentate stream. This new approach is safer for workers and characterized by a reduced environmental impact because hairs are not dissolved and can be removed separately (Cassano et al. 1998).

Leather Processing, Chromium Recovery

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In the tannage operation tanning agents are used in order to prevent the leather from chemical and thermal degradation. The most common tanning agent is the chromium basic sulfate. It enters the pores of the skin by a diffusion process to react with the collagen carboxyl groups and to form inter- and intramolecular cross-linking which results in physical, chemical, and biological stability.

The exhausted bath coming from the chromium tannage contains about 30 % of the

initial salt content and it is normally sent to a cleaning-up plant. Here chromium salts end up into the sludges creating serious problems for their disposal.

Chromium recovery from tanning exhausted baths represents a significant economical advantage for the leather industry in terms of its reuse and for the simplification of the depolluting process of global effluents.

An integrated process based on a preliminary ultrafiltration (UF) of the spent liquor followed by a nanofiltration (NF) treatment of the UF permeate has been proposed as a technically viable method for recovering chromium salts from spent tanning liquors (Cassano et al. 1996, 2007). The UF process allows a marked reduction of suspended solids and fat substances. The concentrated chromium solution obtained in the NF process can be reused for the preparation of new tanning baths. The NF permeate can be reused in the pickling step because of its high content of chlorides (Fig. 1).

Leather Processing, Deliming-Bating

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The deliming step is carried out to reduce the excess of liming agents used in the previous unhairing operation by using acids and/or acidic salts. Since the pH must be slowly lowered, ammonium salts are commonly used for this purpose. In the bating operation, skins are treated with proteolytic enzymes in order to open the fibrous structure of skins, increasing their softness.

Generally, deliming and bating operations are performed in the same drum. Wastewaters from these operations are characterized by high nitrogen content, coming from both the hide structure

and from the ammonium sulfate used as chemical auxiliary.

In order to reduce the nitrogen concentration in the deliming/bating exhausted bath, the replacement of ammonium salts by carbon dioxide (CO₂) and the reuse of wastewater and chemicals after membrane filtration (MF or UF) of the exhausted liquor has been proposed (Gallego-Molina et al. 2013).

MF or UF membranes lead to a remarkable reduction of COD and fat substances of the exhausted liquor (Cassano et al. 2001). The permeate solution can be reused for the preparation of new bating baths or as washing water (Fig. 1), providing environmental and economic benefits due to the water consumption reduction and the reduction in nitrogen and salt discharge.

Lipid Coverage of a Regenerated Cellulose Membrane: Effect on Ion Transport

Juana Benavente and Virginia Romero

Departamento de Física Aplicada I, Universidad de Malaga, Facultad de Ciencias, Malaga, Spain

The modification of solid substrates and membranes using biomaterials is an attractive field of research for developing new devices such as biosensors, structured multilayers, biomembrane mimetics, biomaterial coatings for therapeutical applications, etc. (Goodsell 2004; Sackmann 1996). Particularly, lipid-layer deposition on membrane supports might improve their biocompatibility, but it might also affect membrane transport parameters and, consequently, its functionality.

Changes in electrical and transport parameters for a hydrophilic regenerated cellulose membrane (RC sample) as a result of lipid surface deposition (RC/LL sample) were studied by measuring impedance spectroscopy (IS) and membrane potential. Lipid-layer (glyceryl tristearate as main lipid with L- α -phosphatidylcholine and sodium taurocholate as surfactants) deposition

on RC supports was already described (Benavente et al. 2011).

Impedance is an a.c. technique for determining membrane electrical resistance and capacitance by measurements performed at different frequencies (Benavente 2009). As was already indicated (Benavente et al. 2011), IS measurements for dry LL-modified membranes showed a reduction in conductivity and dielectric constant when compared with original regenerated cellulose support, estimating a thickness of ~ 2 nm for the LL. Figure 1a shows a comparison of Z vs frequency plots for hydrated RC and lipid-layer RC/LL membranes, where differences associated with electrode-membrane interface ($f < 5$ kHz) and bulk membrane can be observed as an indication of lipid coverage of RC support and its effect on the reduction of water (or electrolyte) adsorption by the cellulose structure.

Membrane potential ($\Delta\phi_{\text{meb}}$) is the electrical potential at both sides of membranes in contact with different electrolyte concentrations, and Fig. 1b shows $\Delta\phi_{\text{meb}}$ values vs NaCl concentration ratio c_v/c_c . Two different $\Delta\phi_{\text{meb}} - \ln(c_v/c_c)$ relationships are observed depending on the concentration ratio values: (i) a Donnan-potential contribution for $0.2 \leq c_v/c_c \leq 10$, which is associated with co-ion (Cl^-) exclusion due to the weak membrane effective charge ($X_{\text{ef}} \sim -0.009$ M);

Lipid Coverage of a Regenerated Cellulose Membrane: Effect on Ion Transport, Fig. 1 (a) Impedance plot. (b) Membrane potential dependence on NaCl concentration ratio. RC ($\square$), RC/LL ($\blacksquare$), and FTC ($\triangle$)

(ii) when $2 > c_v/c_c > 10$, the higher contribution seems to correspond to the diffusion potentials as a result of the different transport of counterions (t_+) and co-ions (t_-) in the membrane. Lipid layer does not seem to affect membrane fixed charge, according to the similar $\Delta\phi_{meb}$ values obtained with RC and RC/LL membranes for the Donnan-potential branch (i), but differences in ion transport number should exist due to their different diffusion-potential contribution ($\langle t_+^{RC} \rangle = 0.74$, $\langle t_+^{RC/LL} \rangle = 0.69$) (ii). For comparison, $\Delta\phi_{mbr}$ values for tomato fruit cutin (FTC), a membrane with lipids as major component (Heredia-Guerrero et al. 2012), are also drawn in Fig. 1b, and its comparison with RC/LL results indicates lower fixed charge ($X_f^{FTC} \approx -510$ – 4 M) but rather similar transport parameters ($\langle t_+^{FTC} \rangle = 0.68$) supporting the reliability of RC/LL values.

These results show small changes in transport parameters associated with LL deposition and open the scope to study natural membranes.

Liquid Chromatography: Organic Carbon Detection (LC-OCD)

Loreen O. Villacorte

FMC Technologies, Separation Innovation and Research Center, Arnhem, The Netherlands

Liquid chromatography – organic carbon detection (LC-OCD) is an analytical technique for identification and quantification of natural organic matter (NOM) constituents in aquatic environments and water-soluble synthetic organic matter in technical waters. This technique has several specific applications including NOM investigation in drinking water, wastewater, and marine waters and quality control monitoring of ultrapure water used in power plants and the semiconductor industry (Huber and Frimmel 1994; Huber et al. 2011). It is widely applied in membrane-based water treatment to characterize the different NOM constituents in the source waters (e.g., Kennedy et al. 2005; Amy et al. 2011; Villacorte et al. 2012), to assess the organic removal efficiency of pretreatment and membrane filtration processes (e.g., Frimmel et al. 2004; Villacorte et al. 2009, 2010; Huang et al. 2011; Zheng et al. 2010), and to identify the NOM constituents that cause fouling in MF/UF and NF/RO systems (e.g., Huber 1998; Henderson et al. 2011; Kennedy et al. 2008; Jiang et al. 2010; Batsch et al. 2005; Zheng et al. 2009).

The principle behind NOM fractionation by LC-OCD is based on three separation processes, namely, size exclusion, ion interaction, and

hydrophobic interaction. Since NOM constituents are highly heterogeneous in terms of size and majority of which are hydrophilic and weakly acidic, size exclusion is considered as the dominant mechanism of separation (DOC-Labor 2006). Size exclusion chromatography (SEC) is

based on steric interactions or physical sieving where the difference in speed of diffusion for smaller and larger molecules is used to identify the different NOM fractions in the mobile phase (e.g., buffered water sample). The stationary phase is a packing of porous beads which allows smaller molecules to diffuse into the bead interior while preventing the larger molecules to diffuse through. As a consequence, larger molecules have less volume to traverse and travel faster through the chromatogram column (shorter elution time) than smaller molecules.

Liquid Chromatography: Organic Carbon Detection (LC-OCD), Table 1 Characteristics of different constituents of NOM identifiable by LC-OCD (www.doc-labor.de; Huber et al. 2011; Batsch et al. 2005)

NOM fraction	Typical size (Da)	Typical composition
Biopolymers	>20,000	Polysaccharides, proteins, amino sugars, polypeptides, TEPs, EPS
Aquatic humics	~1000	Humic and fulvic acids
Building blocks	300–450	Weathering and oxidation products of humics
LMW neutrals	<350	Mono-oligosaccharides, alcohols, aldehydes, ketones, amino acids
LMW acids	<350	All monoprotic organic acids

The modern LC-OCD technology is mainly attributed to the works of Stefan Huber in the early 1990s when he successfully improved the sensitivity of the LC/DOC (predecessor of LC-OCD) developed earlier at the Engler-Bunte Institute in Karlsruhe, Germany (http://www.doc-labor.de/). The current LC-OCD system has an online organic carbon detector (OCD), UV detector (UVD), and organic nitrogen detector (OND) to continuously measure the relative signal response of organic carbon, UV, and organic nitrogen, respectively, at different retention

Liquid Chromatography: Organic Carbon Detection (LC-OCD), Fig. 1 Typical LC-OCD chromatogram of NOM in surface water (DOC-Labor 2006)

times. In principle, the analysis technique is as follows: (1) injection of buffered particle-free water sample to a chromatographic column to separate fractions of NOM, (2) nondestructive UV detection at 254 nm wavelength, (3) organic carbon detection based on high-sensitivity TOC analysis, and (4) simultaneous detection of organic nitrogen in bypassed samples after the UV detector (see detailed specifications by Huber et al. 2011). The chromatogram data generated by the three detectors are processed using a customized software program (ChromCALC, DOC-Labor, Karlsruhe) to calculate organic carbon concentrations of biopolymers, humic substances, building blocks, low molecular weight (LMW) acids, and neutrals fractions of NOM based on area integration of the fractional peaks. The lower limit of detection of this technique was reported to be in the low-ppb range for individual fractions (Huber and Frimmel 1991). The typical size ranges and chromatograms of the different NOM fractions detectable by LC-OCD are shown in Table 1 and Fig. 1, respectively.

Liquid Crystal Polymer Membranes

P. C. van H. Kuringen, A. P. H. J. Schenning and D. J. Broer

Department of Chemical Engineering and Chemistry, Group Functional Organic Materials and Devices (SFD), Eindhoven University of Technology, Eindhoven, The Netherlands

Liquid crystals (LCs) combine properties of both liquids and crystals and can be organized in a variety of nanostructured polymer films with a monolithic structure. Therefore, polymer-based LCs are ultimately suited as membrane with an accurately controlled nanoporosity. Nanoporous

membranes that have a large surface area to volume ratio are of great current interest for their potential application in filtration, separation, ion conductivity, drug delivery, and catalysis. The small pore size in these materials (less than 1 nm) makes discrimination between molecules and ions based on size and shape possible.

LCs can self-assemble in a variety of phases that have orientation order and, in some cases, positional order. For the construction of nanoporous membranes, various phases have been used. Well-known examples are hexagonal or columnar, lamellar or smectic, and cubic phases (Fig. 1).

One-dimensional pores are made from LCs with either a hexagonal or a columnar phase. These phases are assumed by disk-shaped LCs: the polar regions are located at the center of the

Liquid Crystal Polymer Membranes, Fig. 1 (a) Examples of chemical structures of the LCs used in the construction of nanoporous membranes. One columnar or hexagonal LC, two smectic or lamellar LC, and three bicontinuous cubic LC. (b) The self-assembly of these

materials to form nanostructured materials, with respectively one, two, or three dimensional pores. The red part represents the pore while the blue fraction is the molecular region (Adapted with permission from reference (Kato 2010). Copyright Wiley, VCH)

columns and the hydrocarbon tails form the surrounding matrix (Fig. 1-a1). If the molecules are well aligned, these one-dimensional pores are interesting for their low tortuosity. The straight pores result in a short path length through the thickness of the material. The cylindrical pores must be continuous through the membrane and uniformly aligned perpendicular to the film surface for optimum transport.

Two-dimensional pores can be created by smectic LCs (Fig. 1-a2). These rod-like LCs self-assemble in lamellar-like structures where the molecules are orientated perpendicular to the layers. A lamellar structure is created with alternating layers of a two-dimensional polymer sheets and two-dimensional pores. However, these sheets do not connect to each other. To circumvent disruption of the film, crosslinkers are used to keep the layers together. To some extent the pore size of the materials can be controlled by the length of the crosslinker.

A bicontinuous cubic phase is used to make nanostructured LC membranes with pores in three dimensions (Fig. 1-a3). Generally, the molecular structure of the LC differs only slightly from the LCs used for the columnar phase. However, the self-assembly is different. Now, no alignment of the pores is needed, since the pores are orientated in three dimensions.

These nanostructured LC polymer networks are used for different membrane applications, such as (anisotropic) ion conductivity (Schenning et al. 2011; Kato 2010) and gas separation (Schenning et al. 2011; Gin et al. 2006). Permeation is the product of diffusion and solubility. Therefore the solubility values of the ions and gases are very important. The local organization of the nanostructured material can promote the solubility of certain species, whereas other molecules are less soluble. This results in higher permeation and selectivity of the desired molecules compared to isotropic material of the same composition. Another application is the nanofiltration of water (Schenning et al. 2011; Gin et al. 2006; Henmi et al. 2012). Molecules smaller than the pore size can pass through the membrane, while

larger molecules (contaminants) are rejected. The presence of charges in the pores of the membranes enables the selective permeation (Gin et al. 2006; Henmi et al. 2012) of ions with a remarkable selectivity: for example, a membrane with pore size of approximately 0.6 nm was shown to transport more divalent sulfate ions than monovalent chloride ions (Henmi et al. 2012). Furthermore, the pore size can be tailored to control the passage of molecules, making them suitable for programmed drug release systems or the confined environment within the material can be used to enhance chemical reactions.

Nanoporous LC polymer membranes can be produced with pore sizes of 1 nm and below. Unique features can be realized, but because of the length of the pores exceeding micrometers, the permeability of liquids is generally low with high pressures necessary to achieve sufficient flow across the membrane. The challenge in this field is to make thinner membrane films of a mechanically robust material that can withstand these high pressures. Research on using mesoporous supporting layers to endure the force while the LC polymer membrane determines the separation characteristics is being undertaken.

Liquid Entry Pressure (LEP or LEPW)

Renzo Di Felice

University of Genova, Genova, Italy

In membrane distillation it is of paramount importance that liquid does not fill the membrane pores, in order to keep membrane efficiency to the highest possible value. To this end hydrophobic membranes are normally used. The hydrophobicity can be quantified through the so-called liquid entry pressure (LEP) parameter, defined as the pressure difference at which liquid penetrates into the membranes pores.

The pressure required to force water through the structure is inversely proportional to the opening size and dependent on the polymeric properties of the membrane. A theoretical expression, based on Young-Laplace equation, enables the estimation of LEP (see, e.g., El Bourawi et al. 2006):

$$\Delta P = \frac{2\gamma \cos\theta}{r}$$

where γ is the liquid surface tension, θ the contact angle between liquid and membrane, and r is the pore radius.

Given the practical difficulty of obtaining the exact value of the above physical parameters, it is not uncommon to estimate LEP experimentally, and Smolders and Franken (1989) described a detailed procedure which should be followed in this case. Basically pressure difference is gradually applied on both side of the membrane until the first drop of the liquid appears on the permeate side (more specific description is given in the suggested reference). Typical values of LEP range from tenth to tens of bars (0.1–20 bar): for example, with liquid water at ambient condition, a PTFE membrane with 95 % porosity, 25 μm thickness, and 3 μm nominal pore size has an LEP of 0.13 bar, whereas a PTFE supported membrane with 75 % porosity, 120 μm thickness, and 0.2 nominal pore size has an LEP of 4.0 bar (Kim and Harriot 1987).

Liquid Membrane Separation

Vladimir S. Kislik

Campus Givat Ram, Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

Liquid membrane separation combines the solvent extraction and stripping processes (re-extraction) in a single step.

This entry has the objective of introducing the reader to the basic definitions of the liquid membrane field, with classification.

The term liquid membrane transport includes processes incorporating liquid-liquid extraction (LLX) and membrane separation in one continuously operating device. It utilizes an extracting reagent solution, immiscible with water, stagnant or flowing between two aqueous solutions (or gases), the source or feed, and receiving or strip phases. In most cases, the source and receiving phases are aqueous, and the membrane is organic, but the reverse configuration can also be used. A polymeric or inorganic microporous support (membrane) may be used as bearer (as in SLM) or barrier (as in BLM technologies) or not used, as in ELM and layered BLM (see respective entries: SLM, ► [Emulsion Liquid Membrane \(ELM\)](#), ► [Silver Recovery by Bulk Liquid Membrane \(BLM\)](#)).

The great potential for energy saving, low capital and operating cost, and the possibility to use expensive extractants, due to the small amounts of the membrane phase, make LMs an area deserving special attention. Liquid membrane systems

are being studied extensively by researchers in such fields as analytical, inorganic, and organic chemistry; chemical engineering, biotechnology, and biomedical engineering; and wastewater treatment. Research and development activities within these disciplines involve diverse applications of liquid membrane technology, such as gas separations, recovery of valued or toxic metals, removal of organic compounds, development of sensing devices, recovery of fermentation products, and some other biological systems.

The general properties of liquid membrane systems have been a subject of extensive theoretical and experimental studies. Some general characteristics of LM processes are as follows:

1. Liquid membrane separation is a rate process, and the separation occurs due to a chemical potential gradient, not by equilibrium between phases.
2. LM is defined based on its function, not the material used in fabrication.

Permeation is a general term for the concentration-driven membrane-based mass transport process. Differences in the permeability produce a separation between solutes at constant driving force. Because the diffusion coefficients in liquids are typically orders of magnitude higher than in polymers, a larger flux can be obtained with liquid membranes. Application of a pressure difference, an electric field, or temperature considerably intensifies the process.

There are several different directions in LM separation classifications: according to module design configurations (see SLM, ► [Emulsion Liquid Membrane \(ELM\)](#), ► [Silver Recovery by Bulk Liquid Membrane \(BLM\)](#) entries), according to transport mechanisms (see ► [Transport Mechanisms with Liquid Membranes](#)), according to applications, according to carrier type, and according to membrane support type. Below, these types of classifications are described and discussed briefly.

According to configuration definition, three groups of liquid membranes are usually

considered (see Fig. 1): bulk (BLM), supported or immobilized (SLM or ILM), and emulsion (ELM) liquid membrane transport. Some authors add to these definitions polymeric inclusion membranes, gel membranes, and dual-module hollow-fiber membranes, but, to my opinion, the first two types are the modifications of the SLM, and the third is the modification of BLM.

According to the transport mechanisms, the LM techniques may be divided into simple transport, facilitated or carrier-mediated transport, coupled counter- or cotransport, and active transport.

According to applications, the LM techniques may be divided into (1) metal separation-concentration, (2) biotechnological product recovery-separation, (3) pharmaceutical product recovery-separation, (4) organic compound separation and organic pollutant recovery from wastewaters, (5) gas separations, (6) fermentation or enzymatic conversion-recovery-separation (bioreactors), (7) analytical applications, and (8) wastewater treatment including biodegradation-separation techniques.

Classification according to carrier type is as follows: (1) water-immiscible, organic carriers, (2) water-soluble polymers, (3) electrostatic, ion-exchange carriers, and (4) neutral, but polarizable carriers.

Classification according to membrane support type is as follows: (1) neutral hydrophobic, hydrophilic membranes, (2) charged (ion-exchange) membranes, (3) flat sheet, spiral module membranes, (4) hollow-fiber membranes, and (5) capillary hollow-fiber membranes.

Module design configurations are used as a rule as basic classification.

Practically, there are a lot of opportunities for liquid membrane separation processes in many areas of industry. The most interesting developments for industrial membrane technologies are related to the possibility of integrating various membrane operations in the same industrial cycle, with overall important benefits in terms of product quality and plant compactness.

**Liquid Permeability**

Alexey Volkov

A.V. Topchiev Institute of Petrochemical
Synthesis Russian Academy of Sciences
(TIPS RAS), Moscow, Russia

Liquid permeability is a liquid flux normalized by driving force – applied pressure difference across the membrane. Liquid permeability can be expressed in volumetric or gravimetric units – $[l/(m^2 \cdot h \cdot bar)]$ or $[kg/(m^2 \cdot h \cdot bar)]$, respectively. This parameter is used to characterize the membrane productivity and passage of pure solvent or solution, in liquid separation process such

as micro-, ultra-, and nanofiltration, reverse and forward osmosis, or hybrid processes like membranes for fuel cell. For commercial membranes liquid permeability is usually given by manufacturers along with value of molecular weight cutoff (MWCO); the last one is characterized the ability of the membrane to reject the solutes with certain molecular weight. Since it is already normalized by driving force of the process, liquid permeability shall be most likely constant value for specific membrane in certain range of operated pressures at constant feed composition and temperature. Due to its uniformity, this parameter allows to compare performance of diverse number of membranes between each other, tested in accordance with different filtration protocols.

In some cases, the liquid permeability can be a function of transmembrane pressure, especially if the membrane material of top layer has a noticeable affinity to the solvent like for organic solvent nanofiltration. Then, increase of pressure difference across the membrane could lead to partial compaction of swollen polymer matrix resulting in some decline of liquid permeability (Volkov et al. 2008). This is typically a reversible effect, and the membrane recovers its transport properties, while the pressure is reduced again. However, if it is accompanied by collapsing of the membrane porous structure or transformation of membrane morphology (e.g., as a result of chemical cleaning), the change in liquid permeability is irreversible. In a case of membrane fouling, there could be a combination of reversible and irreversible decline in liquid permeability, and partial recovery of membrane performance is possible after regeneration stage (Drioli and Giorno 2010).

Liquid permeability can be determined from filtration experiments in dead-end or cross-flow regimes. Ideally, no difference between two regimes shall be expected for filtration of pure solvents or dilute solutions of solutes with no specific interaction with membrane material. Meanwhile, it is preferable to carry out the filtration test in cross-flow membrane cell with high linear velocity in order to minimize concentration polarization effect or membrane fouling during the filtration of real mixtures (e.g., ground or wastewater).

Liquid-Liquid Membrane Extraction

► Membrane Based Solvent Extraction

Lotus Effect

Wolfgang M. Sigmund¹ and Shu-Hau Hsu²

¹Department of Materials Science and Engineering, University of Florida, Gainesville, FL, USA

²Department of Energy Engineering, Hanyang University, Seoul, Republic of Korea

Lotus leaf (*Nelumbo nucifera*) has become the epitome of natural superhydrophobic surfaces and has long been considered as a sacred symbol of purity for thousand years in oriental culture due to its impressive self-cleaning feature, where leaves remain unsmudged even being immersed into muddy water. Water contact angle on lotus leaf is reported above 160° with few degrees of roll-off angle. Therefore, *lotus effect* is sometimes a synonym for superhydrophobicity or self-cleaning nowadays. Although the effect has long been noticed for several generations, a systematically detailed investigation was not carried out until 1997 where more than 200 water-repellent plants were studied via scanning electron microscopy (Neinhuis and Barthlott 1997). The study reveals the secret of lotus leaf, which, not surprisingly, attributes to its combination of surface roughness and chemical substances. Hydrophobicity and self-cleaning of lotus leaf are believed as a mechanism to resist harmful microorganism bounding to the leaf surface, since water is usually required for the germination.

The lotus leaf is covered by small protrusions (Fig. 1a) called papillae with their average diameter and height about 10 μm. The papillae are further covered by an additional layer of epicuticular waxes, generated from epidermal cells (Fig. 1b). These wax crystals are presented in submicron size and in crystalline tubules with water contact angles of about 95–110°, which is considered hydrophobic. The epicuticular waxes play a practically important role as they are not only to provide hydrophobicity but to generate an additional roughness in a smaller length of scale other than micron-sized bumps. The absence of wax crystals, i.e., dropping hot water onto the leaf, will totally eliminate the superhydrophobicity (Liu et al. 2009). The

Lotus Effect, Fig. 1 SEM micrographs of lotus leaf showing its relatively rough surface covered by small micron-sized protrusions (a) and submicron-sized wax crystals (b) (Hsu 2010)

kind of hierarchical roughness on superhydrophobic surfaces seems to play a crucial role, but the detailed mechanism is not yet completely clear. A general benefit suggested is to repel both macro- and micro-scope water droplets (Nosonovsky and Bhushan 2007). Surfaces with only one scale of roughness repelled macroscopic droplets fairly well, while the condensation may easily form microscopic droplets between the grooves of the surface structure.

Low Fouling Membranes

Bijay P. Tripathi

Department of Nanostructured Materials, Leibniz Institute of Polymer Research Dresden, Dresden, Germany

Membrane fouling – a common hindrance to the advancement of water treatment and

separation membrane technologies, including microfiltration, ultrafiltration, nanofiltration, and osmosis processes – diminishes process productivity, raises operating costs, and shortens membrane life span. Fouling is the deposition of retained particles, colloids, macromolecules, salts, etc., at the membrane surface or inside the pore, and at the pore walls. Fouling reduces the membrane flux either temporarily or permanently. The decrease of permeate flux or irreversible membrane fouling is recognized as the main problem in the application of membrane filtration technologies. Several types of membrane fouling have been introduced including inorganic fouling or scaling, colloidal fouling, organic fouling, and biofouling. A schematic representation is given in Fig. 1. Among them, the formation of biofilms on the membrane surfaces or membrane biofouling has been regarded as the most serious problem. The biofouling or biofilm formation starts with the adsorption of proteins and humic substances on membrane surfaces which serves as nutrient for microorganisms (Banerjee et al. 2011; Lejars et al. 2012). The two major approaches to combat surface fouling are based on either preventing foulants from attaching or degrading them. It is generally accepted that an increase in hydrophilicity offers better fouling resistance because protein and many other foulants are hydrophobic in nature (Rana and Matsuura 2010). The high hydrophilicity leads to a high surface hydration which is generally considered

Low Fouling Membranes, Fig. 1 Schematic representation of different types of fouling

the key to nonspecific protein adsorption resistance, organic fouling, microorganisms attachment, etc., since a tightly bound water layer forms a physical and energetic barrier to prevent the adsorption to the surface. While protein-resistant coatings may also resist bacterial attachment and subsequent biofilm formation, in order to overcome the fouling-mediated risk of bacterial infection, it is highly desirable to design coatings that are bactericidal. More recently, hydrophilic coatings using 3,4-dihydroxyphenylalanine (DOPA) and dopamine have been used to modify the surface of microporous polyethylene (PE), polyvinylidene fluoride (PVDF), and polytetrafluoroethylene (PTFE), polysulfone, etc. membranes. The strong adhesive properties of these compounds formed films that attached well to the hydrophobic membranes and decreased the contact angle from 50° to 30° . PEG-modified

polydopamine coatings showed additional resistance to protein and bacterial adhesion.

Compared with the traditional hydrophilic antifouling membrane surfaces, amphiphilic membrane surfaces engineered by the “forced surface segregation” method were demonstrated to exhibit ultralow membrane fouling. The amphiphilic surfaces bearing mixed brush architecture comprised of both hydrophilic blocks and low surface energy blocks are also suggested to be potential antifouling agents. Hydrophilic blocks generated fouling-resistant hydration layers, whereas low surface energy blocks which formed amounts of nonadhesive microdomains played a major role in repulsing the foulants away from the surfaces. Surface modification with zwitterionic molecules and polymers is believed to be the most effective method to counter all types of fouling (Tripathi et al. 2013). Zwitterionic surfaces and

membranes can be obtained by reacting different sultones with amine group containing polymers such as chitosan, polystyrene-poly-4-vinylpyridine block copolymer, etc. Incorporation of nanoparticles into polymeric filtration membranes such as silica, Al_2O_3 , and TiO_2 etc. also reported to enhance the antifouling performance of the membranes because the presence of hydrophilic nanoparticles in the polymer matrix enhances its overall hydrophilic behavior. Nano-sized TiO_2 has received significant interest for its high hydrophilicity, chemical stability, and antibacterial properties (Mansouri et al. 2010). In addition, anatase TiO_2 could serve as a photocatalyst to degrade pollutants during wastewater treatment while having an antimicrobial effect in the presence of UV.

LTA Zeolite Membranes

Yanshuo Li

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, CAS, Dalian, China

LTA zeolite membrane is one of the most well-studied zeolite membranes for the separation of light gases and dewatering of organics. LTA (Linde type A) zeolite has a three-dimensional pore structure, consisting of secondary building units (SBUs) 4, 6, 8, and 4-4 (Meier et al.). An example material is NaA zeolite (Linde type A sodium form) with chemical formula of $\text{Na}_{12}\text{Al}_{12}\text{Si}_{12}\text{O}_{48} \cdot 27\text{H}_2\text{O}$. The unit cell of NaA zeolite is cubic ($a = 24.61 \text{ \AA}$) with Fm-3c symmetry. The pore diameter of NaA zeolite is defined by an eight-member oxygen ring with size around $4.3 \text{ \AA}$. Generally, LTA zeolite membranes exist in the form of composite membranes, for which porous ceramic supports, typically alumina tubes, are usually used as substrates. The effective LTA zeolite separating layer is usually in the thickness of several microns (Fig. 1).

The most used strategies for the synthesis of LTA zeolite membranes are in situ synthesis and secondary (seeded) growth. Microwave techniques combining with these strategies have been applied for the synthesis of LTA zeolite membranes (Li et al. 2008). As compared with conventional hydrothermal synthesis, microwave synthesis of zeolite membranes has the

LTA Zeolite Membranes, Fig. 1 (a) Framework structure of LTA zeolite, (b) typical SEM image of a NaA zeolite single crystal, (c, d) typical SEM image of a LTA zeolite membrane

advantages of shorter synthesis time, better membrane performance, and easier to scale up.

LTA zeolite membrane has been extensively studied for the separation of light gas mixtures, e.g., H_2/CH_4 , O_2/N_2 , and $\text{n-C}_4\text{H}_{10}/\text{i-C}_4\text{H}_{10}$ gas pairs. The observed separation factors beyond the selectivities predicted from Knudsen diffusion are attributed to the so-called molecular sieving function. Another important application of LTA (particularly NaA) zeolite membranes is for removing water from various organics via pervaporation (PV) or vapor permeation (VP), thanks to its ultramicroporous channel structure and its hydrophilic nature. Nowadays, VP dewatering technology based on NaA zeolite membranes has been widely used in the industries of chemistry, bioenergy, electronics, pharmaceuticals, etc. Compared with azeotropic distillation, pressure swing adsorption (PSA), and polymeric membranes, zeolite membrane can remarkably reduce the energy consumption for dewatering of organics (Van hoof et al. 2004).

LTA Zeolite Membranes in Pervaporation

Yanshuo Li
State Key Laboratory of Catalysis, Dalian
Institute of Chemical Physics, CAS, Dalian,
China

LTA Zeolite Membrane in Pervaporation. Pervaporation (PV) or vapor permeation (VP) is a membrane-based separation process which

LTA Zeolite Membranes in Pervaporation, Table 1 Typical PV/VP performances of LTA zeolite membrane for dewatering organics

Feed solution (10 wt.% of water)	Temperature [°C]	Water flux (kg/m ² h)	Separation factor
Water/methanol	65 (PV)	0.6	116
Water/ethanol	65 (PV)	1.0	10,000
Water/ethanol	120 (VP)	3.1	10,000
Water/n-propanol	110 (VP)	2.5	10,000
Water/i-propanol	65 (PV)	1.8	10,000
Water/ethyl acetate	65 (PV)	1.2	10,000
Water/acetone	50 (PV)	0.9	10,000
Water/i-propylamine	105 (VP)	3.2	10,000

shows a high efficiency for the separation of azeotropes and close-boiling mixtures (Huang 1991). In general, zeolites with low Si/Al ratio can be adopted to produce hydrophilic pervaporative membranes for dewatering of organics, as exemplified by LTA, FAU, SOD, and T-type zeolites (Bowen et al. 2004). Among those, LTA zeolite membranes exhibit the highest water to alcohol selectivity up to present, owing to its lowest Si/Al ratio and proper pore size (0.4 nm) that can block organic solvent molecules bulkier than water. LTA zeolite membranes have been widely used for dewatering various organics, including alcohols, aldehydes, ketones, ethers, esters, amines, and amides. Typical performances of LTA membrane are listed in Table 1.

LTA zeolite membrane is the first zeolite membrane to be used in large-scale industries for the dehydration of alcohols (Morigami et al. 2001). Nowadays, commercial LTA zeolite membranes (in NaA form) can be bought from the Japanese company, the Nano-Research Institute Inc. (XNRI), a 100 % subsidiary of Mitsui & Co., the European alliance between Smart (UK) and Inocermic, and most recently the Chinese company, HST Co. Ltd., located at Dalian.

Compared with azeotropic distillation and pressure swing adsorption (PSA), LTA zeolite membrane can remarkably reduce the energy consumption for dewatering of organics. Taking the production of anhydrous ethanol as an example, LTA zeolite membrane-based VP process can

reduce the consumption of steam by 40 % and cooling water by 30 % compared with PSA, respectively.

Macrocapsules

Carles Torras Font

Bioenergy and Biofuels, Catalonia Institute for Energy Research (IREC), Tarragona, Catalonia, Spain

Solid material with a circular cross section (or with circularities near 1). Typical sizes of macrocapsules (also named capsules) are between hundreds of micrometers to millimeters. Macrocapsules have a thick porous wall with a small empty core (or nonexistent empty core) (Pena et al. 2009). This characteristic causes the differentiation between them and macrospheres, which are similar but have a dense and thin wall and a large empty volume inside (Lakshmi et al. 2012).

A main use of macrocapsules is to store compounds inside, which are released in a controlled way and from different parameters (Pena et al. 2009). First of all, there should be a driven force that usually is concentration gradient. Secondly, permeability occurs through the wall due to convection and diffusion. Depending on the type of process, each of them can be the predominant. For instance, considering macrocapsules with dense and thick wall, where only a concentration gradient occurs, diffusion is predominant and allows releases that can last several days (Zhang et al. 2005). On the other hand, the release process can start after an external stimulus to the

wall (i.e., light) (Bogdanowicz et al. 2013), which can cause its breaking and the immediate release of the macrocapsule contents (thus, convection being the predominant mechanism).

Often, macrocapsules are manufactured from polymer due to the simplicity of the process, capacity to control the porous structure of the wall, and cost (specially compared with inorganic materials). Immersion precipitation (a type of phase inversion) can be used to obtain macrocapsules. First, the polymer is dissolved in a solvent. Second, drops are obtained (for instance, with a needle). Finally, drops are immersed in a bath containing the non-solvent, which makes the polymer precipitate and obtain the macrocapsules (Gumi et al. 2009). Conditions of this process allow controlling the porous structure of the wall. Several variables exist: type of polymer, polymer concentration, type of solvent, type and composition of the non-solvent, bath temperature, etc. The compound to be stored is usually added when the macrocapsule is being fabricated and when the polymeric fluid is obtained.

Two main characterizations are performed with macrocapsules: release experiments and physical characterization of the macrocapsule to check their porous structure, hydrophilicity, etc. (Zhang et al. 2005). The second one is performed using the same methods as for flat sheet membranes: mercury porosimetry, scanning electron microscopy (SEM), contact angle, etc. To check the wall porous structure with SEM, the macrocapsule

Macrocapsules, Fig. 1 SEM cross section micrograph of a broken macrocapsule, showing the wall porous structure

should be broken (not cut to avoid wall damage). It can be performed using a cryotome or breaking the capsules within liquid nitrogen after swelling (i.e., ethanol) (Zhang et al. 2005; Torras et al. 2007) (Fig. 1). An option to check visually the porous structure of the macrocapsule without breaking it is by using a confocal laser scanning microscopy after swelling the macrocapsule with a proper fluorescent agent (i.e., rhodamine) (Lamprecht et al. 2000).

Macroporous, Mesoporous, and Microporous Membranes

Lidietta Giorno, Emma Piacentini and Fabio Bazzarelli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Macroporous membranes consist of a solid matrix with defined holes or pores which have diameters larger than 50 nm (Strathmann et al. 2006). These types of membranes are used in driving force pressure process such as microfiltration (MF) and ultrafiltration (UF). They can be classified according to:

1. The type of materials: organic (polymers) and inorganic (glasses, metals, and ceramics)
2. Their structure: symmetric and asymmetric
3. Their configuration: flat sheet, hollow fiber membrane, capillary, and tubular

The separation of solutes by macroporous membranes is mainly a function of molecular size and pore size distribution. The methods are used for making membranes are phase inversion, sintering, stretching, track etching, template leaching, slip casting, and sol-gel process.

Mesoporous membranes consist of a solid matrix with defined holes or pores which have diameters in intermediate range between 2 and 50 nm (Strathmann et al. 2006).

Membrane type	macro-porous	meso-porous	micro-porous	non-porous			
Pore size (nm)	> 50	2 - 50	< 2	no permanent pores			
Separated components							
 suspended solids	 viruses	 bacteria	 colloids	 proteins	 sugars	 soluble salts	 gases/vapours

Macroporous, Mesoporous, and Microporous Membranes, Fig. 1 Schematic classification of membranes, related processes, and separated components

Mesoporous membranes are used mainly for nanofiltration (NF) process. A hydrostatic pressure is applied to transport molecule mixture mass across the membrane. They can be classified according to:

1. The type of materials: organic (polymers) and inorganic (glasses, metals, and ceramics)
2. Their structure: symmetric and asymmetric
3. Their configuration: flat sheet, hollow fiber membrane, capillary, and tubular

The methods are used for making membranes are phase inversion, sintering, stretching, track etching, template leaching, slip casting, and sol-gel process.

The separation of solutes by mesoporous membranes is a function of molecular size, pore size, distribution and electrostatic interaction.

Microporous membranes consist of a solid matrix with defined holes or pores which have diameters smaller than 2 nm (Strathmann et al. 2006). They can be classified according to:

1. The type of materials: organic (polymers) and inorganic (glasses, metals, and ceramics)
2. Their structure: symmetric and asymmetric
3. Their configuration: flat sheet, hollow fiber membrane, capillary, and tubular.

This type of membrane can be used for gas separation and dialysis.

The transport is based on diffusion model. The driving force for gas separation and dialysis is represented by pressure and concentration gradient respectively.

The methods are used for making membranes are phase inversion, sintering, stretching, track etching, template leaching, slip casting, and sol-gel process.

The schematic representation of such classification is illustrated in Fig. 1.

Macrosolute

Radoslav Paulen
Department of Biochemical and Chemical Engineering, Technische Universität Dortmund, Dortmund, Germany

Macrosolute represents an operational term from the field of membrane filtration which denotes solute(s) of particle size(s) larger than ones that pass through a membrane (microsolute) of a

Macrosolute, Fig. 1

Comparison of cross-flow and dead-end filtration in terms of permeate concentration

specified pore size or permeability limit. Membrane filtration may be used to treat such solution (system with macrosolute, microsolutes, and solvent) to concentrate valuable macrosolute in this solution and to get rid of (or dilute) lower molecular weight impurities (Fig. 1).

Distinction of species considered as macrosolute depends on membrane process which is used to treat the solution (Cheryan 1998). In case of:

- Microfiltration – macrosolute is represented by suspended particles and bacteria bodies.
- Ultrafiltration – macrosolute presents macromolecules (typically proteins) and species with larger particle sizes
- Nanofiltration – dissociated acids and divalent salts, sugars, and species with larger particle sizes can be concentrated in solution.
- Reverse osmosis – only water passes through the membrane, and thus the term macrosolute stands for any other species present in the solution.

Magnetic Membranes

Zbigniew J. Grzywna

Department of Physical Chemistry and Technology of Polymers, Silesian University of Technology (SUT), Gliwice, Poland

Magnetic membranes are membranes that show a measurable, nonzero, magnetic induction. Since we consider the membranes for separation, they belong only to two classes, i.e., polymeric (organic) and inorganic (ceramic) (Baker 2004; Li 2007). In both types of matrixes the magnetic powder can be dispersed, and after the membrane is formed, it is exposed to a strong magnetic field for final magnetization. Depending upon the size of the magnetic powders used as fillers, we can have: milli-, micro-, and finally nanomagnetic membranes. The process of formation is crucial in case of magnetic membranes. So far the classical casting methods have been used (Rybak et al. 2009; Dudek et al. 2012) by which the polymer solution with a magnetic powder in it is kept under the weak magnetic field to prevent the powder from sedimentation and to stimulate the formation of pores. The final structure of pores is crucial for transport properties of magnetic

Magnetic Membranes, Fig. 1 Fractal and regular clusters of magnetic particles in the magnetic membrane's cross-section

membranes. There are quite a few options here. Namely, pores can form a cluster (or a percolating cluster) of fractal or nonfractal topology, pores can form a regular inhomogeneous network that can show the $D(x)$ dependence, and, finally, the two-phase system can be obtained, i.e., metallic powder – polymer bulk in case when sedimentation is allowed (no magnetic field during casting).

These cases can be illustrated in Fig. 1.

It is interesting to notice that C and D of the regular inhomogeneous membranes can be produced by compacting magnetic powders and then magnetized in a strong magnet. A strong magnetic gradient across the membrane can be obtained in this way.

A suitable mathematical description of the separation process through such membranes follows (please, note that only one component of the mixture is sensitive to the magnetic field, like oxygen in the oxygen-nitrogen mixture):

There are two distinguished cases in the mathematical description of the above (for the mixtures of two components):

1. The system is weakly coupled, i.e., the individual components do not “see” each other being transported with almost no influence of the other. In such case the description reads (Strzelewicz and Grzywna 2007; Rybak et al. 2009):

$$\begin{aligned}\frac{\partial c_1}{\partial t} &= D_{11} \frac{\partial^2 c_1}{\partial x^2} + D_{12} \frac{\partial^2 c_2}{\partial x^2} - k \frac{\partial c}{\partial x} \\ \frac{\partial c_2}{\partial t} &= D_{22} \frac{\partial^2 c_2}{\partial x^2} + D_{21} \frac{\partial^2 c_1}{\partial x^2}\end{aligned}$$

with initial and boundary conditions

$$\begin{aligned}c_1(x, 0) &= 0 & c_1(0, t) &= c_1^0 & c_1(l, t) &= 0 \\ c_2(x, 0) &= 0 & c_2(0, t) &= c_2^0 & c_2(l, t) &= 0\end{aligned}$$

For the most favorable case $D_{12} = D_{21} \approx 0$, and D_{11} and D_{22} are constant.

When taking into account the structure and morphology (case A) of the separation membranes, we have to refine this simple description by replacing and D_{11} and D_{22} (Krasowska et al. 2012):

$$\frac{\partial c_i}{\partial t} = \frac{D_{0i}}{x^{d_f-1}} \frac{\partial}{\partial x} \left(x^{d_f-\theta-1} \frac{\partial c_i}{\partial x} \right)$$

where:

c_i – concentration of the species i

D_{0i} – diffusion coefficient of a membrane with no magnetic powder

d_f – the fractal dimension of the magnetic membrane structure which may be estimated by the box-counting method for a cross section or a face optical microscopy image of the membrane

θ – the scaling coefficient for the variance of the diffusive front $\langle x^2 \rangle \sim t^{\frac{2}{2+\theta}}$

or (case B) (Borys et al. 2011b):

$$\frac{\partial c_i}{\partial t} = \frac{\partial}{\partial x} \left(D_i(x, B) \frac{\partial c_i}{\partial x} \right)$$

where:

c_i – concentration of the species i

D_i – diffusion coefficient of species i , which depends upon the position (to reflect the inhomogeneous structure of magnetic particles in the membrane along its thickness)

and upon the magnetic field B (to introduce the magnetization dependent reorganization within the membrane structure and permeating particle interactions).

For case B the Knudsen diffusion equation should be used (Kruczek et al. 2006).

2. A coupled system, i.e., a system where its component transport is affected by the presence of the others. There is a few alternative ways of describing such systems (Grzywna and Stolarczyk 2005). One of the less popular but very effective is the choice of hyperbolic diffusion equation (Grzywna and Łuczka 1991; Grzywna and Stolarczyk 2005; Borys and Grzywna 2006; Borys et al. 2011a). Using this idea we can write:

$$\frac{\partial c}{\partial t} + \tau \frac{\partial^2 c}{\partial t^2} = D(x) \frac{\partial^2 c}{\partial x^2} + \frac{1}{2} D'(x) \frac{\partial c}{\partial x}$$

where τ is the correlation time during which test particle moves in a fixed direction and then after it is perturbed to choose a new direction. $D(x)$ is the diffusion coefficient.

Please note that the functional form of $D(x)$ provides modelling of both attractive forces, responsible for correlation, when $D(x)$ is an increasing function of x and repulsive forces otherwise.

Magnetic Nanoparticles

Zbigniew J. Grzywna and Przemysław Borys
Department of Physical Chemistry and
Technology of Polymers, Silesian University of
Technology (SUT), Gliwice, Poland

Definition

Magnetic nanoparticles are types of nanoparticles that respond to magnetic field. According to the meaning of the term “nano,” they should fit in the range between 1 and 100 nm.

Magnetic nanoparticles are types of nanoparticles that respond to magnetic field. According to the meaning of the term “nano,” they should fit in the range between 1 and 100 nm (Gubin 2009). Such size can be sufficient to strip a magnetic material down to a single magnetic domain which may correspond, for example, to a diameter of 15 nm for Fe or 55 nm for Ni (Lu et al. 2007).

The single-domain limit follows easily from the consideration of the alignment of magnetic moments within a ferromagnetic particle (a typical example of magnetic order used in magnetic nanoparticles (Gubin 2009)). The spin-exchange interaction, which is responsible for the ferromagnetic properties of the substance, tends to align the

Magnetic Nanoparticles,**Fig. 1** Energetic state of a magnetic particle in relation to the internal magnetic moment structure

magnetic moments in a single direction (Morrish 1965; Feynman et al. 1963) which however causes an increase in the magnetic field, surrounding the magnetic particle. The energy density of magnetic field surrounding the magnet reads (Feynman et al. 1963):

$$W = \frac{B^2}{2\mu_0}$$

Looking at the Fig. 1 below, the case on the right displays a lower magnetostatic energy, because the field lines outside the material point in the opposite directions and cancel out (Morrish 1965; Feynman et al. 1963). It seems thus that the partition into two domains is desired from an energetical point of view, but the spin-exchange interaction makes the situation look more complex. The spin-exchange interaction provides a tendency to align spins in the same direction, and the formation of a domain that is oriented antiparallel to the other violates this tendency in the region of a domain wall (Morrish 1965; Feynman et al. 1963; Spaldin 2011).

The spin-exchange interaction is very strong. It was proposed by Weiss (Morrish 1965) that the magnetic energy of a dipole under the spin-exchange interaction should be sufficient to enforce order within a domain until the thermal energy exceeds it at Curie temperature (the temperature after which a ferromagnetic material behaves like a paramagnetic material) (Spaldin 2011). Taking as an example the Curie temperature equal to 1,000 K, the equivalent Weiss field acting on a single Bohr magneton could be estimated as being equal to:

$$B_W = \frac{k_B T}{\mu_B} \approx 1500 \text{ T}$$

This is very large compared to the normal fields of strong magnets, which may reach 1.25 T for a FeNdB magnet (Bauer et al. 1996). However, the spin-exchange field acts only on molecules that are closely localized in space (in the atomic range).

For a very small particle, the energy lost due to the spin-exchange interaction while forming a domain with antiparallel-oriented magnetic moment is larger than the energy gain in magnetostatic energy. As the size of magnetic particles becomes larger, the magnetostatic energy grows (in proportion to the number of magnetic dipoles, so to the magnet volume, $V \sim r^3$). At some size the perturbation in the spin-exchange energy related to creation of a domain wall (which affects a thin layer of unaligned magnetic dipoles, so it is proportional to the surface $S \sim r^2$) becomes less than the gain in magnetostatic energy. At this point a domain is formed. This happens for Fe at a diameter of 15 nm and for Ni at a diameter of 55 nm for a spherical particle (Lu et al. 2007).

Except for the magnetostatic and spin-exchange energies, there are also additional energetic contributions related to magnetization like: magnetocrystalline anisotropy (there exist directions in which the magnetization is easier) and magnetostriction (changes in length of the domain due to magnetic field that create strains) (Spaldin 2011).

The single-domain magnetic particles may behave in a different manner depending on their size. For larger particles the magnetocrystalline anisotropy effects matter more (they are

proportional to the volume of magnetic particle) while for smaller particles this energy contribution drops below the level of thermal fluctuations (Lu et al. 2007; Spaldin 2011). As a consequence, the large particles can be magnetized and resemble considerable coercivity (field required to drop magnetization down to zero in a magnetized particle) and remanence (the magnetization which remains after the external field is removed). Moreover, such particles exhibit different magnetization properties in different directions (depending on whether the field direction is parallel or perpendicular to the easy axis of magnetization).

The magnetization curve for large single-domain particle is shown in the following Fig. 2:

Case (a) represents the magnetization in a direction of the easy axis. The particle is spontaneously magnetized in some direction, and to magnetize it in a reverse manner, one has to rotate the magnetization through the hard direction which requires a considerable external field (Spaldin 2011).

In case (b) the magnetization occurs in a direction that is perpendicular to the easy axis and the removal of the external field causes the magnetization to vanish by going back to the preferred easy axis (Spaldin 2011).

Finally, when the magnetic particle is small enough, the abovementioned effects cease to matter, and the particle's magnetic moment undergoes variations due to the thermal fluctuations, averaging to zero. The particle behaves then like a giant paramagnetic atom and therefore is called a superparamagnetic particle (Lu et al. 2007; Spaldin 2011). To be more specific, the review (Lu et al. 2007) provides a relaxation time formula

to reverse the magnetization in a single-domain particle. It reads:

$$\tau = \tau_0 \exp\left(\frac{E_{\text{aniz}}}{k_B T}\right)$$

where $\tau_0 \approx 1\text{ns}$ and $E_{\text{aniz}} = K_{\text{eff}}V$ are the anisotropy energy, proportional to the particle's volume. The temperature that is on the edge of the superparamagnetic behavior is called the blocking temperature.

It is worth mentioning that the superparamagnetic particles, due to their extreme magnetic moment (which can be around $10,000 \mu_B$), allow to measure the whole magnetization curve predicted by the Langevin (or Brillouin) equation within a normal range of external magnetic fields (e.g., up to 1 T), without the need to cool the system down to extreme temperatures (Spaldin 2011).

The magnetic nanoparticles can be made from various types of materials. The most recognized is a ferromagnet (Gubin 2009), where a magnetic domain is characterized by a strict alignment of the magnetic moments (Griffiths 1999). The other is a ferrimagnet (Gubin 2009), where two subpopulations of magnetic moments exist that partially align in an antiparallel manner, canceling out part of the magnetization. This causes strong interactions between molecular spin-exchange fields of the molecules composing a ferrimagnet which, among the others, results in a complex temperature dependency of magnetization (Spaldin 2011). Finally, there are also antiferromagnetic nanoparticles (Gubin 2009; Lu et al. 2007). The antiferromagnetic materials are characterized by a

Magnetic Nanoparticles,

Fig. 3 A shift in the hysteresis of a ferromagnetic nanoparticle with antiferromagnetic shell

full compensation of the magnetic moments in the bulk of the material (Spaldin 2011), which however leaves a possibility to exhibit a magnetic moment due to surface spins (Gubin 2009).

The synthesis of nanoparticles involves many approaches. The first approaches related to mechanical grinding were of limited use for metals due to their malleability (Gubin 2009). The bottom-up methods were developed, where the nanoparticles are grown from metal precursors (Gubin 2009). In such approaches one must face a problem of how to obtain a narrow size nanoparticle distribution. This relates to the problem of separation between the nucleation and growth time scales. Possible approaches in this regard involve coprecipitation, thermal decomposition of organometallic precursors (at high temperature they decompose, releasing metal which nucleates at sufficiently high concentration and then, as the growth starts and concentration drops, only growth continues), use of microemulsions, and hydrothermal synthesis (Lu et al. 2007).

The resulting particles need to be protected (e.g., from oxidation), and one needs to prevent them from agglomeration (Gubin 2009; Lu et al. 2007). This involves a coating of the nanoparticles with shells that can be surfactants and polymers (agglomeration can be prevented by electrostatic repulsive charges of the coating or by steric repulsion), inorganic components like silica, carbon, precious metals (which have low reactivity) or oxides (Lu et al. 2007).

An interesting variant of a coating is a coating of ferromagnetic nanoparticle with antiferromagnetic shell. In such case the interaction of ferromagnet and antiferromagnet (under the

spin-exchange) results in “pinning” of the magnetization to a certain direction. This causes the hysteresis loop of a ferromagnet to shift on the external field axis from the center to a side, because one of the magnetizations becomes unfavorable with respect to the alignment of the magnetic moments of an antiferromagnet (Lu et al. 2007; Spaldin 2011). The figure below that illustrates this idea is sketched after (Spaldin 2011). Observe that in the lower left corner, the alignment of the ferromagnet (FM) with respect to antiferromagnet (AFM) is not favorable (Fig. 3).

The magnetic particles have been applied to the membrane processes, for example, in works (Strzelewicz and Grzywna 2007; Rybak et al. 2009, 2012; Borys et al. 2011) devoted to the enrichment of air in (paramagnetic) oxygen, where micrometer grained particles were used, and in further projects nanoparticles were applied (Dudek et al. 2013, 2012; Strzelewicz et al. 2013; Krasowska et al. 2012). Recently the magnetic nanoparticles were applied in the artificial gill project (Velianti et al. 2014).

²Department of Biomedical Engineering, University of Arkansas, Fayetteville, AR, USA

Synonyms

Environmentally responsive membranes; Multifunctional responsive membranes; Responsive membranes; Smart membranes; Stimuli-responsive membranes

Introduction

Responsive membranes represent a new class of advanced membranes that respond to an external stimulus (Bhattacharyya et al. 2012; Wandera et al. 2010). They are a subset of multifunctional membranes where the membrane performs more than one function simultaneously. The development of responsive membranes has been inspired by biological membranes such as skin and epithelial tissue. The barrier properties of biological membranes can be modulated by environmental conditions such as temperature, humidity, presence of a specific ion, etc. Responsive membranes mimic this behavior allowing for modulation of membrane performance by environmental conditions. In general, in the case of porous membranes, responsive behavior is imparted by grafting responsive polymer layers onto the membrane surface. For nonporous membranes the responsive groups are often part of the membrane polymer (Husson 2012).

Stimuli-responsive membranes make use of the interplay between membrane structure and changes in polymer conformation, polarity, and reactivity (Darvishmanesh et al. 2015). Responsive behavior occurs in two steps: an environmental trigger causes a conformational and/or property transition at the microscopic level which is then amplified to a macroscopically measurable change in membrane performance. Responsive behavior is a result of changes in polymer chain conformation and/or property. Changes in polymer chain conformation and property are due to variations in protonation or deprotonation, hydrophilicity/hydrophobicity, charge density and distribution, solvation free energy, etc. The conformational change is driven thermodynamically to minimize the Gibbs free energy of the polymer/solvent system (Du et al. 2010).

Types of Stimuli

Responsive behavior may be categorized according to the type of stimulus used to elicit polymer conformational and/or property changes

M

Magnetically Responsive Membranes, Fig. 1 Types of stimuli (Reprinted from *Current Opinion in Chemical Engineering*, vol number: 8, Siavash Darvishmanesh,

Xianghong Qian, S Ranil Wickramasinghe, *Responsive membranes for advanced separations*, 98–104, 2015, with permission from Elsevier)

(Darvishmanesh et al. 2015). Figure 1 (Darvishmanesh et al. 2015) gives a schematic representation of the three types of stimuli: direct, indirect, and field induced. Direct stimulation is specific. The responsive groups on the membrane respond to a specific chemical or biological cue. For example, pH-responsive groups respond to changes in pH (H^+ ion concentration) (Himstedt et al. 2013a; Gugliuzza 2013; Wee et al. 2013). A carboxylic group (e.g., acrylic acid) at pH below its pK_a is protonated leading to its decreased hydration and de-swelling effect. The polymer network swells when the pH exceeds its pK_a as the carboxylic groups become deprotonated and repel each other. Thus membrane permeability can be adjusted. In the case of pH-responsive groups, a number of different weak base and acid groups respond to a specific chemical cue, H^+ ions in solution.

Solution ionic strength is another example of a direct stimulus and can affect the degree of polymer swelling in a number of ways. The presence of salt ion and its type and concentration affect charge interactions in the membrane/solution system. It affects the degree of swelling for pH-responsive membranes. Salt ions can cause charge screening thus limiting the amount of swelling. Strong acid and base groups such as quaternary amines are insensitive to solution pH but respond to changes in ionic strength (Husson 2012). In addition poly (zwitterion)-based multilayer membranes have also been shown to respond to solution ionic strength (de Grooth et al. 2014). However unlike weak polyelectrolytes such as weak acids and weak bases, increasing ionic strength leads to an increase in swelling.

Biologically inspired responsive groups include (i) antigen-responsive membranes

(Zhang et al. 2007; Lu et al. 2003), (ii) redox/thiol-responsive groups (Wong et al. 2008; Cerritelli et al. 2007; Ghosh et al. 2009), (iii) enzyme-responsive membranes (Ulijn 2006), and (iv) glucose-responsive membranes (Chu et al. 2004). In these cases a chemical or biological cue directly interacts with a specific chemical groups on the membrane surface. Thus they are much more specific than the pH and ionic strength-responsive group describe above.

Indirect stimulation, like direct stimulation, involves mass transfer to the responsive groups. However unlike direct stimulation, changes in polymer conformation/property occur due to changes in the thermodynamic environment and not to a specific interaction with a chemical or biological cue. Most temperature-responsive polymers display a lower critical solution temperature (LCST). A common example is poly (N-isopropylacrylamide) (PNIPAM). PNIPAM is a hydrogel that is water soluble when the temperature is below its LCST. Above its LCST, the polymer becomes hydrophobic and will phase separate. When PNIPAM chains are attached to a membrane surface, the grafted polymer layers swell and de-swell when the local temperature fluctuates below or above the LCST. Previous studies have shown that conformational switching can lead to the release of adsorbed foulants (Wandera et al. 2011, 2012; Tomer et al. 2009). The LCST of thermo-responsive polymers is strongly affected by the salt ion, its type, and concentration. An increase in concentration will lead to a decrease in LCST. The actual decrease in ionic strength depends on the specific ion present in solution. Recent studies suggest that modulation of LCST by solution ionic strength could be used to develop high-performance ligands for applications such as membrane-based hydrophobic interaction chromatography (Wu et al. 2014; Himstedt et al. 2013b).

Ultrasound represents another method of indirect stimulation. Ultrasound-responsive membranes have been reported for biomedical applications such as controlled drug release. To date most responses to ultrasound waves lead to irreversible cleavage of weak bonds in the polymer structure. Consequently, unlike the

other responsive mechanisms described here, ultrasound-responsive membranes tend to undergo irreversible transformations (Li et al. 2010; Zhang et al. 2009). Development of reversible ultrasound-responsive polymers that undergo reversible transformations could be an area of future development.

Field-induced responsive behavior is fundamentally different to the direct and indirect responses as no mass transfer is required. Three types of external field, electric, magnetic, and electromagnetic waves, have been considered in the past. Electric field-responsive membranes shrink, swell, or twist in response to an external electric field due to the interaction of charged species with the external field. These changes in polymer confirmation can be used to control solute permeation through the membranes. In addition development of fouling-resistant membranes based on desorption of adsorbed solutes due to changes in polymer conformation induced by changes in an external electric field has been described (Wandera et al. 2010).

Magnetic field-responsive groups such as magnetic nanoparticles are usually physically entrapped within the membrane structure or immobilized onto the membrane surface. Changes in an external magnetic field can cause movement and/or heating of these magnetically responsive groups. Recent studies indicate that movement of magnetically responsive polymer chains attached to the membrane surface can suppress concentration polarization during nanofiltration (Himstedt et al. 2011; Yang et al. 2013). In addition magnetically responsive polymer chains attached to the inside pore surface of microfiltration membranes can be used to modulate membrane permeability by applying an external magnetic field (Himstedt et al. 2012).

Electromagnetic radiation such as UV, IR, etc. has been used to trigger structural transformations of functional species such as azo groups (Ishihara et al. 1984; Ishihara and Shinohara 1984; Kinoshita et al. 1986). For example, photo-responsive polyethersulfone (PES) membranes were prepared from blending PES with azobenzene(Azo) and β -cyclodextrin(β -CD). The water permeability of the membranes was

tested under light irradiation at 450 and 365 nm, respectively. At 450 nm, the membrane pores close and water flux decreases due to the complex formation between Azo and β -CD. By changing irradiation wavelength to 365 nm, the membrane pores open due to complex dissociation between Azo and β -CD, and the membranes show higher permeability.

Outlook

Though very much in its infancy, development of responsive membranes offers numerous opportunities for designing high-performance membranes for future separations needs. It is likely that more complicated responsive mechanisms that involve a cascade of stimuli-response interactions will be developed analogous to biological membranes. It is also likely that computational simulations will provide valuable guidance when developing the appropriate nanostructures for these advanced membranes.

Maleic Anhydride Production by Membrane Reactor

Miguel Menendez

Department of Chemical and Environmental Engineering, University of Zaragoza, Zaragoza, Spain

Maleic anhydride is a valuable intermediate product in the manufacture of polyester fiber, succinic acid, tetrahydrofuran, tartaric acid, and several other chemicals. Most of the maleic anhydride is produced by the oxidation of butane with VPO catalyst. This reaction is unique because no other commercial process achieves the insertion of three oxygen atoms in one paraffin molecule in a single step using molecular oxygen. The catalyst is a complex mixture of vanadium and phosphorous oxides, which is often close to the chemical composition of vanadyl pyrophosphate, but in fact the oxidation degree of vanadium varies between +4 and +5 depending on the operating conditions.

Industrial operation is limited by need to avoid explosive atmospheres, which requires low butane or low oxygen concentration. In conventional reactors a low oxygen concentration would imply a too low butane conversion, which would be economically unsuitable. Therefore the industrially employed approach, both for fixed and fluidized bed reactors, is to feed a low butane concentration (typically below 2 %) in air. This approach implies the use of large feed and product flows, increasing the operating and capital costs. The use of a membrane reactor allows the operation with a large butane concentration (up to 10 % butane) but avoiding the coexistence in a given point of large butane and oxygen concentrations (Mallada et al. 2000), in a similar way as when membrane reactors are used for oxidative dehydrogenation. A critical point in this kind of reactor is to avoid too low oxygen concentrations, since a reducing atmosphere changes the oxidation degree of vanadium, with a catastrophic decrease in selectivity.

A way to decrease the risk of vanadium reduction is using CO₂ as inert gas. In fact, there are experimental proofs that under reaction conditions, CO₂ is not fully “inert” but can contribute to achieve a more oxidized catalyst (Mallada et al. 2002; Xue et al. 2001).

Another factor that may contribute to improve the maleic anhydride yield in a membrane reactor is the catalyst bed configuration. If the catalyst bed is located around the membrane, instead of inside, the achievable yield increases. A mathematical model of both reactors explains this result by the differences in radial partial pressure profiles (Pedernera et al. 2000).

Finally, in order to apply a membrane reactor industrially, the temperature control is critical. While fixed bed reactors use a bath of fused salts to keep the catalyst bed temperature under control, this approach would not be feasible in membrane reactors. A method proposed to control the temperature in a membrane reactor is to surround the reactor with a fluidized bed. The high isothermicity and excellent heat exchange are well-known characteristics of fluidized beds, and the same oxygen containing stream that is permeated through the membrane can be used to keep

the bed fluidized. This configuration has been employed in a pilot plant (Alonso et al. 2001).

Manganese Removal by Liquid Membranes

Pietro Argurio

Department of Environmental and Chemical Engineering, University of Calabria, Arcavacata di Rende, Italy

Manganese is the chemical element having the symbol Mn and atomic number 25. It is an essential trace nutrient in all forms of life: it serves as a necessary constituent of metalloproteins including enzymes since it optimizes enzyme and membrane transport function. Although the toxicity of manganese compounds is lower than those of other widespread metals, such as nickel and copper, both its excess and deficiency in the body can cause serious impairment of vital physiological and biochemical processes. Excessive manganese intake is most frequently associated with the so-called manganism, a rare central nervous system disorder, characterized by symptoms similar

to Parkinson's disease (weakness, monotone and slowed speech, tremor, disorientation, memory impairment, anxiety, and hallucinations).

Manganese compounds, in which it has various oxidation states, are widely used in the industry. Manganese dioxide is used in dry cell batteries as a depolarizer and in glassmaking as a drying agent. Depending on their oxidation state, manganese ions have various colors and are used industrially as pigments. The permanganates of alkali and alkaline earth metals are powerful oxidizers, so that they are used as a bactericide and algicide in water treatment and as an oxidant in organic chemical synthesis. Since manganese is used in these and other different industrial processes, its separation and/or recovery from the various liquid effluents or wastewater is of practical value.

A variety of separation processes for metal ions have been developed for industrial needs, including precipitation, inorganic and polymeric adsorption, evaporation, and reverse osmosis. Such techniques produce water within international health standards but entail some drawbacks.

Solvent extraction procedures have proven to be very useful in the separation and/or recovery of metal ions from aqueous media, but they involve high capital and operating costs due to large inventory of solvent, especially in the case of dilute solutions. Thus liquid membrane has been proven to be a very powerful technology.

A liquid membrane (LM) is a layer of an organic phase (the so-called LM phase) that separates two aqueous solutions. An extractant (carrier), promoting the so-called facilitated transport from the donor phase (feed) to the acceptor phase (strip), may be dissolved in the organic phase (Molinari et al. 2009a, b). LM-based processes offer a technology with a lot of advantages over conventional separation techniques. The main advantages are (i) combination of extraction and stripping processes in a single stage, resulting in a low solvent consumption; (ii) uphill transport against concentration gradient; and (iii) small amounts of extractant needed, resulting in the possibility to use very selective carriers, which sometimes are not very cheap.

A widely used important acidic extractant in hydrometallurgy in metal separation and/or

recovery is di(2-ethylhexyl)phosphoric acid (D2EHPA). It is extensively used also in the extraction and recovery of manganese from neutral and weakly acidic solutions using supported liquid membrane and emulsion liquid membrane (Mohapatra and Kanungo 1992). Some studies (Yongtao et al. 1992) considered the simultaneous extraction and concentration of cadmium and manganese from aqueous solutions obtaining recoveries of cadmium and manganese in the range of 92–100 %. Recently a novel method for Mn(II) extraction from sulfuric acid solutions has been proposed (Sadyrbaeva 2011) which involves electrodialysis and a bulk liquid membrane containing D2EHPA as the carrier. To accelerate the ion transfer through the liquid ion-exchange membrane, an electric field was applied. Operating in this way, the electrodialytic process (unselective) was coupled with the liquid membrane-based process, which provides greater selectivity and permeability with respect to the traditional solid ion-exchange membrane. Complete removal of Mn(II) from a feed solution containing 0.01 mol/L of MnSO_4 and a maximum extraction degree of 88 % was obtained under optimized conditions.

Liquid Membrane as Pre-concentration Technique

Manganese could be accumulated in tissues and body fluids, like blood serum and urine. Considering the very low concentration of trace elements (manganese in our case) in these fluids, a pre-concentration step before analysis is required. According to results from a recent study (Soko et al. 2003), the D2EHPA-based supported liquid membrane technique can be used to extract and pre-concentrate Mn(II) from water, milk, and blood serum.

Mass Intensity

Adele Brunetti

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane operations are well known for their modularity, compactness, and flexibility; therefore, they can be considered as new operations developed in the logic of process intensification. Recently, new metrics for comparing membrane performance with those of conventional units have been introduced (Curzon et al. 2001; Brunetti et al. 2011, 2014). These new metrics take into account the size, the weight, the flexibility, the yield, and the modularity of the plants. They are useful for having an immediate indication of the eventual gain that a membrane operation can offer with respect to a traditional one. In this sense, they are useful also for selecting the proper separation technology for a specific process.

Among them, mass intensity is a measure of the exploitation of the raw material with respect to final production or recovery of the desired product, and it can be intended as a measure of the efficiency of the process.

In order to compare different systems, it can have different definitions: it can be calculated taking into account the product and its fraction recovered (Eq. 1) as valuable product with respect to the total mass fed. It can also be calculated as the ratio between the amount of product and its fraction recovered with respect to the steam and cooling water necessary to carry out the process (Eq. 2). In the ideal situation, the mass intensity would approach 1 which means that all the inlet mass has been converted or recovered as valuable product.

$$\text{Mass Intensity}_1 = \frac{\text{Total inlet mass}}{\text{Mass of desired product recovered}} \quad (1)$$

$$\text{Mass Intensity}_2 = \frac{\text{Steam and cooling water required}}{\text{Mass of desired product recovered}} \quad (2)$$

Mass of Immobilized Enzyme

Lidietta Giorno¹ and Francesca Militano^{1,2}

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²University of Calabria, Rende, Italy

Enzymes can be immobilized on the membrane surface or within the membrane structure by various techniques, including physical entrapment, chemical adsorption, and chemical attachment.

Regardless of the immobilization mechanism, the methodology in general includes the use of an initial enzyme solution (or feed), of known proteic enzyme concentration and volume, that is fed to the membrane or in which the membrane is immersed. After a certain time, the solution is collected (final solution or retentate), the volume is accurately measured, and washing solutions are used to remove the enzyme present in the system that is not immobilized in a stable way.

The amount of immobilized enzyme can be determined by the mass balance between mass present in the initial, final, and washing solutions:

$$\text{mass}_{\text{enz. imm}} = \text{Mass}_{\text{initial}} - \text{Mass}_{\text{final}} - \text{Mass}_{\text{washing}}$$

The enzyme mass in each solution can be determined by the enzyme concentration and volume of the solution (mass = concentration * volume). The enzyme concentration can be measured by a protein assay method (such as biuret reaction, Lowry method, Bradford assay, bicinchoninic acid (BCA) assay (Sapan et al. 1999)). These methods rely on the denaturation and hydrolysis of the protein in corresponding amino acids followed by the reaction of amino acids (in general those bearing more reactive functional groups) with reagents that form complexes that absorb at specific wavelength in the visible spectrum.

A calibration curve prepared with protein standard solution permits to determine the concentration of the unknown sample. The use of the same type of immobilized protein as standard (if available in pure form) or pure proteins with similar amino acid content as the one used for the immobilization is necessary to have true protein estimation and accurate mass balance. In general, BSA (bovine serum albumin) is used as a protein standard.

The direct measurement of protein absorbance in the UV range (usually at 280 nm) is sometimes reported. However, it is not accurate enough since protein denaturation strongly affects the absorbance intensity, and there are evidence that when a protein is recycled along a circuit or pressed through a pore, the conformation may open (even though this might be to an extent that does not deactivate the enzyme).

The BCA assay can be used for the direct determination of covalently bound or adsorbed proteins on membranes. In the BCA assay, the colored complex that develops is a result of a secondary reaction not involving the protein itself. The principle of the assay relies on the formation of a Cu^{2+} amino acid complex under alkaline conditions, followed by reduction of the Cu^{2+} to Cu^{1+} forming a purple-blue complex that is stable and water soluble. Since the purple complex is water soluble, the color is formed and released into the supernatant instead of remaining associated with the membrane.

The membrane with the immobilized protein can be directly immersed on the reaction reagent. After the required incubation time, the membrane can be removed and the absorbance of the supernatant is read at 562 nm. The immobilized protein amount is directly determined by comparison to a standard curve obtained in the same way by using the soluble protein (or the protein standard).

The direct BCA method is therefore well suited for determining membrane-bound protein with enhanced sensitivity. It is fast and less subject to errors inherently encountered during the combination of loading and wash buffers required to do the mass balance method. This is a destructive method and therefore specific membrane samples have to be dedicated to the analyses. The amount of immobilized enzyme on the sample of membrane used for reaction rate or catalytic activity analyses is assumed similar to the one detected as it is carried out in parallel in the same conditions.

However, when selecting a method, it must be taken into account that some substances (such as buffering salts and chelators) and the membrane itself may interfere with the protein assay.

For kinetic studies of immobilized enzyme, where the accuracy of the amount of enzyme is extremely important, a cross-check with both methodologies is advised.

Mass Transport Equations

Renzo Di Felice

University of Genova, Genova, Italy

Synonyms

[Mass transfer resistance](#)

Mass transfer is a phenomenon, generated by a concentration difference, by which a component

is transferred from a point to another. The introduction of a mass transfer coefficient is a simple way to quantify this phenomenon. Mass transfer coefficient is defined as the ratio between the component flux and the driving force generating the flux (Cussler 1997),

$$k = \frac{\text{rate of component flux}}{\text{driving force}} \quad (1)$$

The unit of the mass transfer coefficient depends on the units used to quantify flux and driving force. For example, if we express fluxes in kmol/m²s and driving force is a concentration difference (kmol/m³) then *k* will have the unit of m/s. However, reader should be aware that different units are sometime used, depending on the circumstances: fluxes can be expressed in mass rather than moles, and driving force can be a partial pressure or a molar fraction difference.

The definition of a mass transfer coefficient could not be simpler but nothing can be said a priori about its numerical value. For the way it has been defined, mass transfer coefficient is a function of the two points considered for the mass transfer, although in the vast majority of cases one point is the fluid phase (gas or liquid) bulk and the other is a system boundary, such as a tube wall or an interface. The coefficient numerical value depends on the specific system considered (flow in pipes, fixed bed of particles, falling liquid film) and on the physical parameters (such as diffusivity, density, viscosity, etc.). As it is most useful for situations where an analytical approach is not practical or too complex, its quantification relies on experimental measurements. Much effort has been devoted to generalize as much as possible data collected from experimental measurements, and this has been done by correlating the data through dimensional parameter, generally involving a suitably defined Sherwood number, containing the mass transfer coefficient, Reynolds number, and Schmidt number, in analogy with observation on heat transfer which correlate Nusselt number with Reynolds and Prandtl numbers. Practical relevant examples are the case of mass transfer taking place for the flow inside a pipe between the phase bulk and the tube wall

$$Nu = 0.026 Re^{0.8} Sc^{0.33}$$

or the flow outside and perpendicular to a capillary bed

$$Nu = 0.80 Re^{0.47} Sc^{0.33}$$

The concept of mass transfer coefficient can also be utilized when transfer between different phases is considered, such as mass transfer between a gas and a liquid phase or mass transfer between fluids separated by a dense membrane.

The definition given in Eq. 1 is still applicable although care must be taken when the driving force is to be quantified. As a descriptive example, let's consider the case of mass transfer of a component *A* taking place between the bulk of gas phase, with *p_A* the component partial pressure and the bulk of a liquid phase, with *C_A* the component concentration. The overall mass transfer coefficient can be defined in this case as the ratio between component A mass flux and overall driving force, a parameter which is given by the "homogenized" difference between *p_A* and *C_A* obtained by substituting the concentration in one phase with the corresponding equilibrium value in the other phase. In other words

$$\text{Driving force} = p_A - HC_A = \frac{p_A}{H} - C_A$$

where *H* is the parameter expressing the partition equilibrium of the component *A* between the gas and the liquid phase (which assumes a constant value if a Henry law type equilibrium applies).

Materials and Structures of Synthetic Membranes

Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synthetic membranes show a large variety in their physical structure and the materials they

are made from. Based on their structure they can be classified in four groups:

- Porous membranes
- Homogeneous dense solid membranes
- Solid membranes carrying electrical charges
- Liquid or solid films containing selective carriers

Furthermore, the structure of membranes may be symmetric, i.e., the structure is identical over the entire cross section of the membrane, or it may be asymmetric, i.e., the structure varies over the cross section of the membrane.

The materials used for the preparation of membranes can be polymers, ceramics, glass, metals, or liquids. The materials may be neutral or carry electrical charges, i.e., fixed ions. The membrane conformation can be flat, tubular, or a hollow fiber. The schematic drawing of Fig. 1 illustrates the morphology, materials, and configuration of some technically relevant synthetic membranes.

⁵Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

Mass transport between two phases through a membrane may be the result of diffusion, convection, or migration depending on the driving forces and the structure of the membrane.

A mass transport process is referred to as *diffusion* when individual components permeate a matrix independent of each other by random movement under the driving force of a chemical potential gradient. The permeation rate in a

diffusion process depends on the magnitude of the driving force, i.e., the chemical potential gradient of the diffusing component and on its diffusion coefficient which is determined by friction between the diffusing component and other components in a mixture.

A mass transport process is referred to as *convection* when bulk flow occurs under the driving force of a hydrostatic pressure difference relative to a matrix which acts as a frame of reference. The flow velocity depends on the hydrostatic pressure difference and hydrodynamic permeability of the matrix which is determined by the friction between the solution and the matrix.

A mass transport is referred to as *migration* when charged components move through a matrix under the driving force of an electrical potential difference. The migration rate depends on the electrical potential gradient and the mobility of the components in the matrix. The mobility of a component is directly related to its diffusion coefficient and is determined by the friction between the migrating component and other components in a mixture.

In membrane processes all three forms of mass transport can contribute to the overall flux. Generally, however, one transport form is dominant while the others contribute to a lesser extent to the overall mass flux. In micro- and ultrafiltration, convection of a bulk solution is the dominant form of transport while diffusion is generally insignificant. In reverse osmosis matter is transported through the membrane mainly by diffusion of individual molecules through a more or less homogeneous membrane matrix, but convection can become significant with high-flux membranes. In electrodialysis migration of ions in an electric field is the dominant form of transport, but under certain process conditions diffusion and convection can also become relevant.

The mass transport through membranes can be described by various mathematical relations. Most of them are semi-empirical, postulating membrane models, such as Fick's law, Hagen-Poiseuille's law, and Ohm's law. A more

comprehensive description, which is independent of the membrane structure and thus of any membrane model, is based on a general phenomenological equation which connects the fluxes of electrical charges and individual components with the driving forces by a linear relation (Onsager 1931):

$$J_i = \sum_k L_{ik} X_k \quad (1)$$

Here J is a flux per unit area and generalized X is a driving force, the subscripts i and k refer to individual components and electrical charges, and L is a phenomenological coefficient relating the fluxes to the driving forces.

For multicomponent systems with fluxes of individual components and electrical charges, Eq. 1 can be written as a matrix in which the diagonal coefficients relate the fluxes to the directly corresponding driving forces and the cross coefficients express the coupling of fluxes with nonconjugated driving forces:

$$\begin{aligned} J_1 &= L_{11}X_1 + L_{12}X_2 + \cdots + L_{1n}X_n \\ J_2 &= L_{21}X_1 + L_{22}X_2 + \cdots + L_{2n}X_n \\ &\vdots \\ J_n &= L_{n1}X_1 + L_{n2}X_2 + \cdots + L_{nn}X_n \end{aligned} \quad (2)$$

Thus, Eq. 2 describes the mass transport through a membrane not only as a linear function of the corresponding driving forces as does, e.g., Fick's or Ohm's law, but it considers also a possible kinetic coupling between different fluxes.

In membrane processes fluxes are the result of spontaneous, i.e., irreversible, processes with a positive entropy production. The relation between the entropy production and the mass transport is given by

$$T \frac{dS}{dt} = \Psi = \sum_k J_i X_k = \sum_i \sum_k L_{ik} X_i X_k \geq 0 \quad (3)$$

Here Ψ is the dissipation function, X is a driving force, the subscripts i and k refer to individual components and electrical charges, and L is a

phenomenological coefficient relating the fluxes to the driving forces.

By introducing Eq. 3 into Eq. 2, it can be shown (Katchalsky and Curran 1965) that the diagonal coefficients are always positive, while the cross coefficients may be positive or negative. For a two-component system which has two driving forces and four phenomenological coefficients, the dissipation function is given by

$$\Psi = (L_{11}X_1 + L_{12}X_2)X_1 + (L_{21}X_1 + L_{22}X_2)X_2 \geq 0 \quad (4)$$

Since the entropy production for all positive and negative values of X_1 and X_2 must be positive, the phenomenological coefficients must satisfy the following relation:

$$L_{11} \geq 0 \text{ and } L_{22} \geq 0 \quad (5)$$

and

$$L_{11}L_{22} - L_{12}L_{21} \geq 0 \quad (6)$$

Thus, the diagonal coefficients must always be positive while the cross coefficient may be positive or negative to satisfy Eq. 4.

The number of the cross coefficients, however, is reduced by the Onsager relation (Onsager 1931) which is given by

$$L_{ik} = L_{ki} \quad (7)$$

Through the coupling of fluxes, it becomes obvious that a transport of components may be obtained without a directly related driving force. The magnitude of the fluxes obtained through a coupling with other fluxes depends on the coupling coefficient. In many cases the coupling between fluxes can be neglected. In some cases, however, it can be significant. For instance, the coupling of water with an ion flux can lead to a significant water transport through a membrane.

Equation 1 provides a very complete description of transport processes through a membrane. The only other boundary condition relevant for a system which contains charge components is that electroneutrality is required at all times on a

macroscopic scale. All phenomena observed in membrane systems, such as osmosis and electro-osmosis, the diffusion of individual components, viscous flow of the bulk solution, the electric current, the buildup of an osmotic pressure, the streaming, and the diffusion potential, as well as the different technically relevant membrane processes, can in principle be described by applying Eq. 1. For most practical applications, however, this equation is rather complex. First of all, it is only applicable close to equilibrium because of the assumed linear relationships between fluxes and driving forces. Furthermore, the many different coefficients are difficult to determine by independent measurements. The treatment becomes even more complicated if the membrane consists of a heterogeneous medium such as a micro- and ultrafiltration membrane where viscous flow is the dominant means of mass transfer in the pores when a hydrostatic pressure is applied as a driving force, but diffusion and migration can exist both in the pore medium and the solid membrane matrix.

However, in many practical applications, kinetic coupling between fluxes can be neglected and Eq. 1 can be reduced to more simple relations, such as Ohm's or Fick's law, and the phenomenological coefficients can be expressed by the electrical resistance or the diffusion coefficient.

Another approach to describe the mass transport in membrane processes is based on a relation developed by Maxwell and Stefan around 1870 and which was extended by Spiegler (1956). In this relation the forces are expressed as a linear function of the fluxes:

$$X_i = \sum_k R_{ik} J_k \quad (8)$$

Here X is a driving force, J is a flux, and R is a phenomenological coefficient relating driving forces and fluxes.

The coefficient R has the dimension of a generalized resistance and is expressed by a unit force divided by a flux. It is related to the coefficient L of Eq. 1 which has the dimension of a generalized conductance and is expressed as flux per unit force by

$$L_{ik} = \left(\frac{J_i}{X_k} \right)_{X_i} \text{ and } R_{ik} = \left(\frac{X_i}{J_k} \right)_{J_i} \quad (9)$$

The Maxwell-Stefan approach is based on the assumption that in a steady state flux, the driving forces acting on a component i are equal to the sum of the friction forces between i and other components in the system.

The flux of a component in a mixture is always expressed relative to another component, which is used as a frame of reference. Thus, the flux J_i of a component i in a mixture relative to a component k is

$$J_i = C_i(u_i - u_k) \quad (10)$$

Here u is the linear velocity of the component and C the concentration.

The flux of an individual component is always proportional to its linear velocity relative to the velocity of another component, which is used as a frame of reference. Thus, the number of independent fluxes in a given system is equal to the total number of components in the system minus the one used as reference. A system containing a membrane with n components, including the membrane, has $n-1$ independent fluxes. In membrane processes generally the fluxes through the membrane are of interest. Therefore, the membrane is used as frame of reference and its velocity is assumed to be zero.

If viscous flow is excluded, the Maxwell-Stefan equation (Wesselingh and Krishna 1990) is given by

$$\begin{aligned} X_i &= \sum_k C_i f_{ik} (u_i - u_k) \\ &= \sum_k C_i \frac{RT}{\mathcal{D}_{ik}} (u_i - u_k) \end{aligned} \quad (11)$$

or

$$J_i = \frac{\mathcal{D}_{ik}}{RT} X_i \quad (12)$$

Here X is the driving force, C is the concentration, u is the linear velocity, f is the friction coefficient, and $\mathcal{D}$ is the Maxwell-Stefan

diffusion coefficient. The subscripts i and k refer to individual components.

Combination of Eqs. 11, 12, and 1 provides the relation between the various terms of the phenomenological equations and the Maxwell-Stefan equations:

$$\sum_i L_{ik} = \frac{1}{\sum_i R_{ik}} = \frac{1}{\sum_i f_{ik}} = \sum_i C_i \frac{D_{ik}}{RT} \quad (13)$$

Equations 11 and 12 provide the same complete description of transport processes through a membrane separating two homogeneous mixtures as does the phenomenological Eq. 1. The only other boundary condition relevant for a system which contains charge components is that electroneutrality has to be fulfilled at all times on a macroscopic scale.

Mass transport in membrane processes can be achieved by applying different driving forces, such as pressure, concentration, or electrical potential gradients to a feed mixture. The different driving forces result in different membrane processes in which also different membrane structures are utilized. In micro- and ultrafiltration, for example, porous membranes are applied that separate the various components of a mixture according to their size. The transport is mainly based on convection and the driving force is a hydrostatic pressure gradient. In reverse osmosis, gas separation and pervaporation dense films are used as selective barrier for the transport of low molecular weight components. The driving force is a hydrostatic or partial pressure difference between a feed mixture and a permeate. The transport is based on diffusion. In dialysis a concentration difference is used to achieve the desired mass transport which is also based on diffusion. In electrodialysis an electrical potential gradient across a membrane leads to a migration of charged components.

The mass transport in the various membrane processes can be described by the phenomenological equations which can be simplified by certain approximations that are based on postulating certain membrane models such as the

solution-diffusion model, the porous membrane model, and the ion-exchange membrane model.

Matrimid® Membranes

Ahmad Fauzi Ismail and Juhana Jaafar
 Faculty of Chemical and Energy Engineering,
 Universiti Teknologi Malaysia, Advanced
 Membrane Technology Research Centre
 (AMTEC), Johor Bahru, Johor, Malaysia

Matrimid membrane can be developed from different types of commercially available polyimide resins such as Matrimid 5218 (3,3',4,4'-benzophenonetetracarboxylic dianhydride and diaminophenylindane), Kapton, Matrimid 5292A (4,4-bismaleimidodiphenylmethane), Matrimid 5292B, Matrimid P84, and Matrimid 9725 (micropulverized version Matrimid 5218) (www.ciba.com; www.huntsman.com). The employment of commercially available polyimide resin was found to be more practical from the economic point of view due to the high cost of synthesized polyimides on the laboratory scale (Xiao et al. 2005).

The Matrimid membranes are commonly prepared via solvent evaporation (Sridhar et al. 2007; Mosleh et al. 2012) and phase inversion (Basu et al. 2010) techniques. The asymmetric (Nistor et al. 2008; Basu et al. 2010) or dense (Shishatskiy et al. 2006) Matrimid membrane can be in flat sheet (Shishatskiy et al. 2006; Aziz and Ismail 2010) or hollow fiber (Dong et al. 2011; Ding et al. 2008; Jiang et al. 2004) form.

Matrimid especially the Matrimid 5218, an extremely popular polyimide, has been extensively studied for gas separation, pervaporation processes, and carbon membrane due to the combination of relatively high gas permeability coefficients and separation factors as well as excellent mechanical properties, high solubility in non-hazard organic solvents, and high glass transition temperature in comparison to polycarbonate, polysulfone, and other materials (Wind 2002; Nistor et al. 2008). The typical permeation properties of Matrimid 5218 are tabulated in Table 1.

The overall performance (in terms of permeability and selectivity) of Matrimid membrane in gas separation processes can be diverse as reported in the open literatures which was due to the several factors such as:

- (i) Operating conditions of gas permeation test
- (ii) Effective (skin layer) membrane thickness (the thinner the selective skin layer is, the better the gas flux will be)
- (iii) Membrane morphology as a consequence of the different conditions of phase inversions of membrane preparation technique
- (iv) Properties of the gas tested

Matrimid® Membranes, Table 1 Typical permeation properties of Matrimid 5218 (David et al. 2011)

Permeability of pure gases (Barrer ^a)		Ideal selectivity
PO ₂	P _{N2}	O ₂ /N ₂
1.32–1.34 ^b	0.185 ^b	7.2 ^b

^a1 Barrer = 10^{-10} cm³ (STP) cm cm⁻² S⁻¹ cmHg⁻¹ = 7.5×10^{-18} m³ (STP) m m⁻² S⁻¹ Pa⁻¹,

^bPure gas Permeation measurement for O₂ and N₂ at 3447.3785 kPa, 25 °C

The weakness of Matrimid membrane is always pronounced by the membrane transport properties that are strongly affected by the gas separation operating conditions such as pressure and temperature that are likely relied to the changes in density, and consequently in the free volume, of the polymer itself (Rowe et al. 2009; David et al. 2011). Hence, the presence of minor components in the feed flow, such as impurities or water vapor, can strongly affect the gas transport mechanism, thus altering the separation performances (Chen et al. 2011). Moreover, its glassy nature may lead to plasticization phenomena at high fugacity of gases and vapors and to aging phenomena that decrease the performances upon time (Tin et al. 2003). These shortcomings limit the Matrimid membrane application particularly in gas separation processes. Due to this awareness, numbers of modification have been reported by researchers to improve the Matrimid membrane properties in order to fulfill the gas separation performance requirement particularly to surpass the Robeson boundary line (Basu et al. 2010). The idea to modify the Matrimid membrane was initiated by the good processability of the polymer itself owing to its carbonyl functional groups (see Fig. 1) that may lead to the donation of electrons to form good interaction with certain electron acceptors (Chung et al. 2003). The modifications were conducted on the Matrimid membrane including the incorporation of mesoporous silica molecular sieve (Kenneth et al. 2002), bromination (Guiver et al. 2002; Xiao et al. 2005), blending with other polymers (Chung et al. 2003), thermal treatment (Krol et al. 2001), and chemical cross-linking (Tin et al. 2003).

Matrimid® Membranes, Fig. 1 Chemical structure of Matrimid

Due to the excellent properties shown by Matrimid membrane, which is desirable for gas separation process, therefore it is worth to accelerate relevant modifications on this promising membrane for better separation performance.

Fleming College, Lindsay, ON, Canada

Synonyms

Physical cleaning

Mechanical cleaning of membranes may be used for the removal of fouling, particularly if other common utilized cleaning practices based on chemical and hydraulic methods do not restore membrane flux. Sustainable membrane performance is hampered by complex fouling phenomena, which occur on the membrane surface or inside the pores, leading to a reduction in productivity and an increase in transmembrane pressure (TMP). Cleaning of the membranes, irrespective of the procedure used, has a knock-on effect to the membrane life expectancy and operational replacement costs (Van der Roest et al. 2002).

The methods used depend upon the separation process and the configuration of the module. The most important aspect during the operation of membranes is to prevent the forming of a cake layer i.e., deposits on the membrane surface. Cake layer formation is predominantly caused by concentration polarization occurring in the liquid boundary layer in front of the membrane. Mechanical cleaning is accomplished by introducing high shear forces at the membrane surface by mechanical action in order to loosen and dislodge the deposits. In general, the mechanical action in membrane systems is provided by using various materials, turbulence promoters e.g., scouring sponge balls or fluidized particles. One of the benefits of using turbulence promoters is that this method does not involve any significant loss in water production during the membrane cleaning.

Sponge balls, made typically of polyurethane foam, are commonly used for cleaning of tubular membrane systems, when treating wastewater and industrial process water, due to their size limitation (Psoch and Schiewer 2006). Sponge balls are typically slightly larger (1–2 mm) than the inner diameter of membrane tubes to ensure an effective scouring of accumulated deposits from the membrane surface. The cleaning action of membrane is obtained by forcing sponge balls down the tubes at high velocity by the application of fluid pressure. Sponge balls are either injected directly to the feed stream and then collected from the retentate using appropriate mesh screens, or are automatically pushed back and forth along the tubes from storage channels on both the inlet and outlet of the module (Scott 1995). The mechanical cleaning by sponge balls can be performed in online and/or offline modes. However, the online mode is more practical as the cleaning process can take place while the plant is in operation, so that this method does not involve any significant loss in water production during the membrane cleaning. The cleaning frequency is much higher, thus the tubes are maintained clean at all times. Mechanical cleaning by sponge balls is most effective at removing soft biological and organic foulants from the membrane surface but not from within the membrane pores (Zeman and Zydney

1996). Sponge ball cleaning has also been combined with chemical cleaning successfully restoring flux (Ebrahim 1994). The removed deposits are gradually disposed of via the waste stream to the local water course. There are many manufacturers of sponge cleaning balls such as Luxx Ultra-Tech Inc., Taprogge, Technos, Water Science of America (WSA), Remington and Schmitz. Several different types of sponge balls i.e., standard, extended life, or abrasive in a variety of hardnesses and sizes are available commercially. Whereas the standard balls are designed for general application, the expanded life balls are only applied for mild fouling problems. The extended life balls are coated with thin smooth skin, which wears out slowly resulting in extended life. Abrasive balls are coated fully or partially with carborundum and are designed for abrading hard deposits in metal tubes only. After being used, sponge balls should be washed out to remove contaminants, thus increasing the longevity of the balls (Web Source). The fouling removal ability of sponge balls depends on many factors such as size, number, hardness, surface texture and age of the balls, the frequency and duration of treatment, and nature of fouling.

In order to select the most appropriate sponge balls the following criteria for ball assessment can be considered (Mustafa Osman Ahmed Hamed et al. 2001):

- Mechanical damage (ball splitting) is caused by the collision of balls with the flow path surfaces. The repeated compression of the balls also leads to mechanical damage by erosion and peeling.
- Shrinking is mainly attributed to the ball material and its temperature tolerance and can be measured by its size and weight.
- Surface wear, which occurs by abrasion due to the deposits in the tubes, is a common phenomenon resulting in loss of ball effectiveness.
- Deformation in the shape of the balls is mainly related to the temperature and pressure tolerance of the balls' material and results in uneven tube cleaning.
- Loss of texture is a major deficiency of balls that restricts the ability of balls to regain their

shape and size. It also results in sticky balls. Ball material should be good enough to withstand higher temperatures and prolonged contact with seawater.

Fluidized particles (glass/steel beads, foam cubes, Kaldnes[®] and Rauschert carriers, granulates). The use of fluidized particles minimize or control concentration polarization and membrane fouling through the enhancement of the convective flow and the generation of turbulences due to the introduction of fluidized particles in the flow conduit or membrane tank. Moreover, fluidized particles continuously mix up the liquid boundary layer in front of the membrane and scour the membrane surface, thereby, preventing membrane fouling and also remove the matter that has already been deposited.

Fluidized glass ($\rho = 2900 \text{ kg/m}^3$) and steel beads ($\rho = 7800 \text{ kg/m}^3$) with diameter ranging from 0.46–1.04 mm to 1.0–2.0 mm, respectively, were successfully applied for cleaning of the tubular polysulfone membranes. Smaller and lighter beads seem to improve permeate flux through the membrane significantly, minimizing the risk of membrane damage (Noordman 2000). Moreover, the use of fluidized particles seems to be especially attractive for liquids with higher viscosity as the risk of membrane damage is reduced with increasing velocity.

Another mechanical cleaning procedure, using polyurethane foam cubes or polyethylene Kaldnes[®] or Rauschert (Bioflow 9) carriers can be applied for membrane bioreactors (MBRs). A MBR process is the combination of a conventional activated sludge process and membrane filtration and is now widely used for municipal and industrial wastewater treatment. The cleaning elements are introduced into filtration tanks equipped with submerged flat sheet membranes to swirl between the membrane sheets and clean them during filtration. MBR operation using of foam cubes with a size of 3–5 mm and polyethylene Kaldnes[®] and Rauschert (Bioflow 9) carriers of 9–10 mm partly removes membrane fouling, thereby increasing the membrane's performance. The use of the cleaning elements, with a 20 %

filling volume of the filtration tank, led to a 35 % increase in filtrate production (Wulf and Orth 2008). One disadvantage of using this cleaning method is that the introduced carriers may damage the membrane and another one is the requirement of big enough gaps between membrane plates (>10 mm), so that the cleaning elements can freely move. Such big gaps between membrane plates are directly related to a lower packing density of membranes, which leads to larger foot print and thus higher costs.

Another novel mechanical cleaning strategy, based on the use of plastic granulates, was developed for continuous cleaning of BIO-CEL[®] modules of Microdyn-Nadir, Germany (company's website) which incorporates the required constructional and hydraulic characteristics (Siembida-Lösch 2011). The mechanical cleaning process using granular material is operated in a loop reactor without interrupting filtration and permeate loss. The process is being supported by the crossflow aeration system and the use of plastic granulates. Granulates, introduced directly into an activated sludge filtration tank, flow upward alongside the membrane forced by the crossflow air. Granulates are returned to the base of the module with the downstream water flow outside the membrane modules where it enters again into the upstream flow. Thereby continuous removing of the cake layer occurs. Granulates are retained in the filtration tank during sludge discharge by suitable sieving systems. Granulates must meet some requirements, to efficiently clean the membranes, i.e.,

- Nonporous, to prevent from the change of density during operation by taking up water and forcing material to settle
- Density >1 kg/L to move freely with the liquid flow in the reactor
- Size <5 mm, as the gap between two BIO-CEL[®] membrane sheets is 8 mm
- Form should be either globular or oval without edges to prevent the damage of membrane material
- Biologically inert, to prevent microbial degradation

The most appropriate specific aeration demand per membrane area (SADm) for the granular material of being moved into the loop is $0.7 \text{ m}^3/(\text{m}^2 \cdot \text{h})$. Operation at higher or lower SADm values can lead to irregular distribution of granulates or to settling in a filtration tank, respectively. Typically, a granulate concentration of 4 kg per m^3 of activated sludge volume is sufficient for an optimal MBR operation treating municipal wastewater, however, it can vary for other applications (Siembida-Lösch 2011). The patented process BIO-CEL[®] MCP (Mechanical Cleaning Process) reduces operating costs as it enables much higher specific flows. This lowers investment costs (smaller membrane area needed) and reduces energy consumption (crossflow) for the entire system. Furthermore, the MCP is suitable for external module cleaning if already fouled and also minimizes chemical demand. The fouling layer formed during the filtration process can be removed safely without causing any damage to the membrane.

Melt Spinning

Khayet Mohamed

Department of Applied Physics, Universidad Complutense de Madrid, Madrid, Spain

Melt spinning is a fiber fabrication technique from polymers or polymer/diluent systems that can be melted. Both fibers (filaments) and hollow fibers can be prepared by melt spinning technique. The polymer is first compressed, heated, and melted by an extrusion screw, then forced to pass through a spinneret of different geometries. The polymer solidifies by cooling (thermal precipitation) after being extruded from the spinneret and then collected by means of take-up wheels. The spinning rate in melt spinning (thousands of meter per minute) is much higher than that used in the dry/wet spin technique (meters per minute) (Mulder 1992).

It is possible to prepare both porous and nonporous hollow fibers by thermal precipitation also known as thermally induced phase separation (TIPS). Figure 1 shows a typical example of the systems used (Khayet and Matsuura 2011; Matsuyama et al. 2003). A given amount of a dope solution (polymer/diluent system) is mixed under a nitrogen atmosphere in the vessel heated at a temperature above the melting temperature of

Melt Spinning, Fig. 1 Schematic diagram of a hollow fiber preparation system via thermally induced phase separation (TIPS) technique (Reprinted from (Matsuyama et al. 2003). Copyright 2003, with kind permission from Elsevier)

the blend. The homogeneous polymer/diluent melt blend is then fed to a spinneret by a gear pump under nitrogen pressure of about 0.2 MPa. The spinneret shows an outer and an inner tube. A diluent can also be introduced into the inner tube of the spinneret to make a lumen of the hollow fiber. The fiber extruded from the spinneret enters in the water bath under a controlled temperature to induce phase separation and solidification by means of polymer crystallization. Simultaneously, the nascent fiber is wound by using a take-up winder at several speeds. The diluent present in the fiber is then following different methods that depend on the type of the diluent. Other than the dope solution, the variables involved in hollow fiber membrane preparation

via the TIPS technique are the air gap distance, which is the distance from the spinneret to water bath or to take-up wheels, the spinning temperature, the water bath temperature, the take-up speed, the spin draw ratio, the extrusion rate of the blend, the flow rate of the diluent in the inner tube of the spinneret, the cold stretching through the air gap, the temperature of the polymer/diluent blend and its composition, etc.

The TIPS technique is caused by a temperature change and typically consists of the following basic steps (Khayet and Matsuura 2011; Lloyd 1990):

- i. A homogeneous solution is first formed by melt blending a polymer and a liquid or solid

having a low molecular weight and a high boiling point, referred to as the diluent (i.e., does not cause dissolution or swelling of the polymer at room temperature). The initial temperature must be less than the boiling point of the diluent and is typically 25–100 °C greater than the melting temperature or glass transition temperature of the polymer. The polymer must be stable at this initial temperature. To avoid confusion, the term diluent will be used instead of solvent, hereafter. The diluent acts as a solvent only when it can dissolve all polymers. When the solvent power decreases sufficiently so that liquid-liquid demixing takes place, the term solvent is not appropriate anymore.

- ii. The hot solution is extruded or spun in the desired shape including a hollow fiber.
- iii. The solution is cooled at controlled rate or quenched to induce phase separation and solidification.
- iv. The diluent(s) that is trapped in the polymer matrix during phase separation and solidification is removed by solvent extraction procedure.
- v. The extractant is removed by evaporation to yield microporous structures if required.
- vi. Posttreatment processing might be applied to improve the desired separation characteristics of the TIPS membrane. Stretching might be included in this step.

TIPS can be applied to a wide range of polymers, including those that cannot be otherwise formed into membranes because of poor solubility in solvent.

The type of phase separation (liquid-liquid phase separation, solid-liquid phase separation, combined liquid-liquid and solid-liquid phase separation) that is likely to occur for a given system (composition and temperature) is indicated by the phase diagram (Khayet and Matsuura 2011; Laxminarayan et al. 1994). This is a useful tool explaining the morphology and bulk structure of TIPS membranes. Polymers such as polyethylene (PE), polypropylene (PP), and poly(2,6-dimethyl-1,4-phenylene ether) (PPE) were used in melt spinning (Khayet and Matsuura 2011).

[Membrane classification](#); [Membrane definition](#); [Membrane function](#)

A precise and complete definition of a membrane that covers all its aspects is rather difficult, even when the discussion is limited to synthetic structures. Various definitions have been reported in the literature, most of them focusing on the

selective properties of the membrane. For example, Lonsdale defined a synthetic membrane as an interphase that separates two phases and restricts the transport of various components in a specific manner (Lonsdale et al. 1982). In new membrane processes, such as membrane contactors, the membrane is a nonselective barrier that separates and contacts two adjacent phases. Therefore, in the most general sense, we can define a membrane as a discontinuous phase between two adjacent phases that permits the exchange of matter, energy, and information between the phases with selective or nonselective properties.

Separation of a mixture in a membrane process is the result of different transport rates of different components through the membrane. The transport rate of a component through a membrane is determined by driving forces such as concentration, pressure, temperature, and electrical potential gradients, as well as by the concentration and mobility of the component in the membrane matrix.

A membrane can be homogeneous or heterogeneous, symmetric or asymmetric in structure (Strathmann et al. 2006). It may be solid or liquid and may consist of organic, inorganic, or biological materials as well as a mixture of them. Membranes made of inorganic components dispersed in the organic matrix are called mixed matrix membranes. Membranes made of biological components contained in organic or inorganic materials are called biohybrid membranes. When membranes are engineered with materials that transfer principles from biology, they are termed biomimetic membranes. Bioinspired membranes are a broader term compared to biomimetic. They are synthetic membranes that mimic the structure and function of their natural counterpart. A biomimetic membrane is also bioinspired, but not necessarily the other way round.

A membrane may be neutral or it may carry positive or negative charges, or functional groups with specific binding or complexing abilities. Its thickness can be less than 100 nm to more than a millimeter. The electrical resistance may vary from more than $1,000,000 \Omega \text{ cm}^2$ to less than $1 \Omega \text{ cm}^2$.

The term “membrane,” therefore, includes a great variety of materials and structures, and a membrane can often be better described by its

function rather than by its structure. Some materials, such as protective coatings or packaging materials, show typical membrane properties and are in fact membranes. Most materials functioning as membranes have the characteristic property in common of restricting the passage of different components in a very specific manner. In some cases, they may restrict the passage of the same component, depending on the state: a hydrophobic polymeric membrane may allow the passage of water as vapor phase but not as liquid phase, as, for example, in membrane distillation. In other cases, e.g., membrane contactors, the porous structure of the membrane material functions as a barrier that keeps in contact two adjacent phases between which a mass transfer occurs and separates them at the same time. In this case the membrane has no direct effect on the transport of various components and is nonselective toward the passing species. The concept of a selective and nonselective membrane is illustrated in Fig. 1 which shows (a) a membrane which is highly selective and capable of separating, e.g., two enantiomers, and (b) a membrane that acts as a barrier between two phases and avoids the mixing of the phases but has no selective properties related to the transport of different components from one phase to the other.

A porous structure represents a very simple form of a membrane, which closely resembles the conventional filter as far as the mode of separation is concerned. These membranes consist of a solid matrix with defined holes or pores which have diameters ranging from less than 1 nm to more than $10 \mu\text{m}$. The macromolecular size of the species to be separated plays an important role in determining the pore size of the membrane to be utilized and the related membrane process. Porous membranes with average pore diameters larger than 50 nm are classified as macroporous, and those with average pore diameters in the intermediate range between 2 and 50 nm are classified as mesoporous. Membranes with average pore diameters between 0.1 and 2 nm are classified as microporous. Dense membranes have no individual permanent pores, but the separation occurs through fluctuating free volumes, by solution-diffusion mechanism (Strathmann et al. 2010).

Membrane (Definition, Function, Structure), Fig. 1 Schematic drawing illustrating (a) a membrane which is selective for the transport of different components such as two enantiomers and (b) a membrane which separates a liquid and a vapor phase and allows passage of vapor molecules but is not selective for the transport of different components

Separated components	gases vapours	sugars	proteins	bacteria	emulsions	colloids

Membrane (Definition, Function, Structure), Fig. 2 Schematic classification of membranes, related processes, and separated components

The schematic representation of such classification is illustrated in Fig. 2.

In pressure-driven membrane processes, the separation of the various components is achieved by a sieving mechanism with the pore diameters and the particle sizes being the determining parameters. In thermally driven membrane processes, the separation is based on the principle of

Membrane (Definition, Function, Structure), Fig. 3 Porous symmetric (a) and asymmetric membrane (b)

Membrane (Definition, Function, Structure), Fig. 4 Schematic diagram illustrating (a) the sieving mechanism of a porous membrane and (b) the solution-diffusion mechanism in a nonporous membrane

phase equilibrium, and the non-wettability of membrane pores is the determining parameter. Membrane structure may be symmetric (Fig. 3a), i.e., the pore diameters do not vary over the membrane cross section, or they can be asymmetric (Fig. 3b), i.e., the pore diameters increase from one side of the membrane to the other typically by a factor of 10–1,000.

The mechanism by which certain components are transported through a membrane can also be very different. In some membranes, for example, the transport is based on viscous flow of a mixture through individual pores of the membrane caused by a hydrostatic pressure difference

between the two phases separated by the membrane. This type of transport is referred to as *viscous flow*. The components that permeate through the membrane are transported by convective flow through macropores under a pressure gradient as driving force and the separation occurs because of size exclusion as indicated in (Fig. 4a). Darcy's Law describes this type of transport. It is the dominant form of mass transport in micro- and ultrafiltration but also occurs in other membrane processes.

If the transport through a membrane is based on the solution and diffusion of individual molecules in the nonporous membrane matrix due to a

Membrane (Definition, Function, Structure), Fig. 5 General classification of membranes

concentration or chemical potential gradient, the transport is referred to as *diffusion*. The separation occurs because of different solubility and diffusivity of components into the membrane material as indicated in (Fig. 4b).

Fick's law describes this type of transport. The diffusion of molecules through homogeneous dense membranes occurs through the free volume elements, or empty spaces between polymer chains caused by thermal motion of the polymer molecules, which fluctuate in position and volume on the same time scale as the molecule permeates. The transition between fluctuating free volumes and individual permanent pores is controversial. In general it is considered in the range of 5–10 Å in diameter.

This form of mass transport is dominant in reverse osmosis, gas separation, and pervaporation but it may occur in other processes, too.

If an electrical potential gradient across the membrane is applied to achieve the desired transport of certain components through the membrane, the transport is referred to as *migration*. Migration occurs in electrodialysis and related processes and is limited to the transport of components carrying electrical charges such as ions.

The general classification of membranes, on the basis of material, structure, and configuration, is illustrated in Fig. 5.

Membrane Aging

Donald R. Paul

Department of Chemical Engineering, Texas Materials Institute, Austin, TX, USA

The term **membrane aging** as used here refers to the physical aging process that occurs over time for a membrane based on a glassy polymer. As polymers are cooled through the region of the glass transition temperature, T_g , the time scale of motions of the polymer chain segments becomes much longer than the time scale of the observation; thus, the material is no longer able to maintain an equilibrium structure like it does above T_g . Thus, glassy polymers exist in a nonequilibrium state that has a higher specific volume (or lower

density) than it would have if it could have maintained an equilibrium state. This situation is illustrated in Fig. 1 that shows a plot of polymer-specific volume versus temperature. The actual state achieved below T_g depends on how the glass was formed and all its prior history. The extra fractional free volume, FFV, the glass has owing to being trapped in this nonequilibrium

Membrane Aging, Fig. 1 Illustration of the specific volume versus temperature *above* (rubbery state) and *below* (glassy state) the glass transition temperature of a polymer. The arrow indicates the path of slow densification of the glass over time

state affects many properties such as gas permeability, P , as seen by the relationship:

$$P = Ae^{-B/FFV} \quad (1)$$

At temperatures below T_g , the material continues to proceed toward its equilibrium (see arrow in Fig. 1), albeit at a very slow rate. This densification process is called physical aging or structural relaxation (Kovacs et al. 1977). This process of aging is thermally reversible meaning that the original state can be restored by heating above T_g . As a result of this densification process or physical aging, all properties like permeability also evolve over time.

It has been observed that the rate of physical aging of glassy polymer films depends strongly on thickness and that this effect is particularly pronounced below thicknesses of less than about $1 \mu\text{m}$, which can be tracked by measuring gas permeability, as seen in Fig. 2 for polysulfone (Huang and Paul 2004). A convenient summary of the experimental techniques used to study these effects of thickness for thin films and contemporary interpretations of the observations has been given by Rowe et al. including the effects of prior history (Rowe et al. 2011).

Membrane Aging, Fig. 2 Effect of physical aging on the oxygen permeability for a series of polysulfone films (at 35°C) (Huang and Paul 2004) (Reproduced with permission of Elsevier (Copyright 2004))

Since gas separation membranes must have a very thin, thicknesses ~ 100 nm, skin or separating layer to achieve high fluxes, they are expected to exhibit similar effects when the polymer is glassy. This may be manifested as a decline in productivity over the lifetime of the module. Of course, much of this aging may have already occurred prior to the membrane being put into service. Even so, this means that the actual permeability of the active layer may be much lower than estimated by thick film (tens of microns in thickness) tests.

Membrane Air Dehydration

► Air Dehydration by Membrane Technology

Membrane Air Stripping (MAS) Process

Ashwani Kumar

Institute of Chemical Process and Environmental Technology, National Research Council Canada, Ottawa, ON, Canada

Contamination of groundwater and wastewater by volatile organic compounds (VOCs), resulting from improper disposal, poses a serious

environmental problem in many areas. Among several methods of removing VOCs, air stripping appears to be the best available technology. However, this method has limitations in term of fouling, larger footprint, and higher capital costs. Recovery of VOCs from water by membrane air stripping (MAS) is an alternate process with a lot of potential (Mahmud et al. 1998). Due to higher surface-to-volume ratio of the hollow fiber membranes, this is the desired format where contaminated water is pumped through the lumen side of the fiber while dry air is passed over the shell side of fibers. Although the overall mass transfer coefficient in MAS is lower than the spray towers but overall volume specific rate of stripping is several times higher in MAS due to higher surface-to-volume ratio. Mass transfer resistances in MAS processes have been studied by many researchers. Semmens et al. (1989) reported individual local liquid phase, local gas phase, and membrane mass transfer resistances for the MAS process using L  v  que (1928) correlations. It was noted that the predicted overall mass transfer coefficient was significantly higher than the observed values. Membrane resistance for polypropylene fibers depended on wetting of pores (Malek et al. 1997). The mass transfer resistance due to the membrane in pure water and aqueous solution containing VOCs were investigated at different airflow values for developing a process. It was found that extent of air or water in the pores contributes to the final resistance. The models were built by considering resistance to the partially air-filled pores. The model prediction agreed well with literature and our own laboratory data for a variety of VOCs (Mahmud et al. 2000, 2002, 2004). Further, there was no significant effect of the initial concentrations of VOCs in water. Based on the above analysis, a laboratory scale study of removal of naphtha components from wastewater showed that up to 92 % of original naphtha could be removed by MAS process (Fig. 1). It was also observed that overall mass transfer coefficients and propensity of stripping depended on the structure of individual naphtha components (Mahmud and Kumar 2012).

[Artificial functional organ](#)

Membrane artificial organs are membrane devices that replace the function of natural organs like artificial kidneys/dialyzers and artificial lungs/blood oxygenators for the purpose of restoring the specific organic functions.

Polymeric semipermeable membranes and membrane processes play a pivotal role in replacement therapy for acute and chronic organ failure and in the management of immunological disease (De Bartolo and Drioli 1998).

Membrane Artificial Organs, Fig. 1 Comparison of hemodialysis polyethersulfone membrane (a) with glomerular membrane (b)

In these devices semipermeable membranes act as selective barriers for the removal of endogenous and exogenous toxins from patient's blood (hemodialysis, hemofiltration, etc.) or for gas exchange with blood (blood oxygenation) (Kawakami 2008). Hemodialysis is an extracorporeal treatment of patients affected by kidney failure. The treatment is intermittent, generally three times weekly for periods between 3 and 5 h depending upon the patient clinical requirements. In hemodialyzer, selective membranes play the same function of kidneys allowing the extracorporeal removal of waste products such as creatinine and urea and free water from the blood when the kidneys are in a state of renal failure. It involves diffusion of small solutes across the semipermeable membrane retaining protein and molecules with high molecular weight. Membranes used in the hemodialyzer device have been engineered in order to have the similar structure of the renal glomerular membrane to ensure a similar performance. Membrane hollow fiber and glomerular capillary employ a cylindrical cross section in order to minimize perimembrane boundary layers and to maximize transport efficiency, have same ratio of wall thickness/cross-sectional diameter, and are composed of linear hydrophilic polymers that rely on van der Waals forces and islands of crystallinity to retain their integrity. Difference is scale: the glomerule has a

diameter of 4–8 μm , and synthetic hollow fiber membranes have diameters in the range of 200 μm . For example, the structure of polyethersulfone membrane that is widely used in hemodialyzer is similar to glomerular membrane. Both have asymmetric structure with a selective skin layer supported by a sponge layer (Fig. 1). This structure confers to the membrane an optimal selectivity and high mechanical resistance.

The first hollow fiber hemodialyzers made of unmodified cellulose were used clinically in the 1960s. Since the first cellulose membranes, significant efforts have been focused on the development of more biocompatible and selective membranes with respect to the clearance of “middle” molecules like β_2 -microglobulin that is known to be associated with many dialysis-related disorders. A variety of synthetic polymers and modified cellulosic materials including polysulfone (PSF), polyethersulfone (PES), polyamide (PA), polyacrylonitrile (PAN), cellulose triacetate (CTA), and hemophan (HP) have been used for preparing hemodialysis membranes (Humes et al. 2006; Su et al. 2008).

Extracorporeal blood oxygenators are used to oxygenate the blood during open-heart surgery. Today, the vast majority of these blood oxygenators use hydrophobic microporous hollow fiber membranes to separate the blood and gas phases.

Membrane Artificial Organs, Fig. 2 Comparison of oxygenator polypropylene membrane (a) with pulmonary alveoli (b)

Oxygen diffuses from the gas phase through the gas-filled membrane pores into the blood. Oxygen in the blood plasma binds to hemoglobin present in the red blood cells. Consequently the rate of oxygen transfer is enhanced compared to the oxygenation of water where the oxygen does not react in the liquid phase (Lewandowski 2000).

Membrane oxygenators in current use utilize microporous, silicon, or polypropylene membranes. Currently, there are three principal types of oxygenator: (a) Plaque oxygenators are built with microporous membranes of expanded polypropylene, folded in a Z shape. In these apparatuses, blood and gas flow in opposite sides of the membrane. (b) Spiral oxygenators utilized silicon membranes that are rolled around a central axis. (c) Hollow fiber oxygenators are manufactured with microporous polypropylene membranes, constituted by hollow fibers or capillary. This is the most common type of oxygenator used currently.

The most common membranes for blood oxygenator have been engineered in order to have morphology close to the pulmonary alveoli. For example oxygenator polypropylene membranes have massive reticulated surfaces deployed as fine, porous, open-cell foams, which remind the saccular form of the alveoli and the very thin alveoli septa (Fig. 2). In the natural lung, blood flows through fine capillaries in the alveoli and exchanges O_2 and CO_2 across a barrier made up of

capillary endothelial cells; in oxygenators blood flows on the outside of a large bore fiber, with diameter of 300 μm , and exchanges respiratory gases across a meniscus that forms across the membrane pore at the interface of blood and gas.

The diffusion of these gases inside the oxygenator depends on the type of material of the membrane and on its thickness and porosity, but it is also influenced by the thickness of the layer of blood in contact with the membrane and by the characteristics of the blood flow (Wickramasinghe et al. 2005).

Liquid-liquid membrane extraction

In membrane based solvent extraction (MBSE) two immiscible phases are in contact with a porous membrane. One of the two phases wets the membrane whilst the other does not wet it (Fig. 1).

In membrane-based solvent extraction mass-transfer between two immiscible solvents occurs

Membrane Based Solvent Extraction, Fig. 1 Schematic of MBSE mechanism at membrane level. F: feed, S: solvent, Sw: solvent in fiber wall. Here is shown the case where the membrane is wetted by the organic solvent

from the liquid/liquid interface immobilized at the pore mouth of the microporous membrane that is not wetted by one of the phases in contact. In this way, dispersion of the liquid phase into the other is prevented. Microfiltration or ultrafiltration membranes are usually used as support to immobilize the interface between the two immiscible phases. In membrane based solvent extraction the membrane has no selective properties, it only serves as support for the immobilization of the interface. Basic information on membrane based solvent extraction are found in Prasad and Sirkar (1992), Reed et al. (1995), Schlosser (2000, 2009).

The solvent can be regenerated by re-extracting the solute in a stripping solution. Figure 2 shows the schematic of a membrane based solvent extraction and stripping using two hollow fiber modules.

Membrane based solvent extraction is often assisted by a carrier that reacts with the solute at the interface immobilized on the first module and it is released at the interface of the second module. Figure 3 shows the case of extraction of lactic acid by a quaternary amine.

In membrane based solvent extraction mediated by carriers, kinetics of extraction reactions should be taken into account as it can play an important role. The concentration dependence of the distribution coefficient of solutes is another parameter to be taken into the account. The solute distribution coefficient influences the concentration gradient and may result in the concentration dependent overall mass-transfer coefficient.

In the literature, studies using models considering the constant mass-transfer coefficient in MBSE (Viegas et al. 1998), or variable distribution coefficients (Escalante et al. 1998; González-Munoz et al. 2004) are reported. Models taking into account reaction kinetics of formation and decomposition of the extractant-solute complex(es) in extraction and stripping interfaces are also discussed (Juang and Huang 1997; Juang et al. 2000; Kubišova et al. 2004; Schlosser et al. 2001). The contribution of resistance based on reaction kinetics to the overall resistance depends

on solute and carrier concentrations. It may range between 30 % and 80 %.

Ionic liquids result very promising in the solvent extraction of organics (Han and Armstrong

2007; Pletnev et al. 2008). Ionic liquids (ILs) are composed of organic cations and organic or inorganic anions that remain in liquid state over a wide temperature range, including room temperature.

The majority of works deals with ILs with imidazoliumcations. A new promising group of ILs based on phosphoniumcations (Bradaric et al. 2003).

Membrane Bioartificial Organs

Loredana De Bartolo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane bioartificial organ is a membrane device containing living cells, which is implanted or integrated into a human to replace for short or long term a natural organ. This device is realized as alternative to organ transplantation or as bridge for supporting patients until the organ transplantation. Every year, many patients die while waiting for an organ transplant. Organs such as the liver, kidney, and lungs are often in very high demand by patients with severe illnesses. Historically, the number of available organ donors has been insufficient to meet the needs of every patient. For a traditional organ transplant to succeed, the donor and patient must be a close biological match. Even when a replacement organ is available, the immune system of the recipient may reject the transplant. Membrane bioartificial organs have been designed to solve this problem. Some examples are represented by membrane bioartificial liver for the treatment of acute and chronic liver disease, bioartificial pancreas as alternative approach to exogenous insulin administration in the case of insulin-dependent diabetes mellitus, bioartificial kidney for people with poorly functioning kidneys, and bioartificial lung for the treatment of patients with end-stage lung disease. Membrane capsules containing dopamine-secreting cells are also being explored for the treatment of Parkinson's disease, a progressive brain disorder characterized by a deficiency of the neurotransmitter dopamine. Immunoprotective membrane cell transplants are being investigated to treat other nervous system disorders. Other membrane bioreactors are used for the adoptive cell therapy for the treatment of malignant diseases or viral infections in the expansion of T lymphocytes (Jagur-Grodzinski 2006).

Membrane bioartificial organs involve the design, modification, growth, and maintenance of living tissues embedded in natural or synthetic scaffolds to enable them to perform complex biochemical functions, including adaptive control and the replacement of normal living tissues. In membrane bioartificial organs, cells are compartmentalized by means of semipermeable membranes that permit the transport of nutrients and metabolites to cells and the transport of catabolites and specific metabolic products to the blood (Drioli and De Bartolo 2006). The membrane must avoid the contact between cells and patient's blood to prevent immunological response and consequent rejection. Membranes act also as means for cell oxygenation and in the case of anchorage-dependent cells as substrata for cell attachment and culture. In these systems, cells come into contact with the membrane surface. Therefore, the response of the cell behavior depends on the surface properties of the used membrane (Morelli et al. 2010). For this reason, membranes should be chosen not only on the basis of their separation properties but also on the basis of physicochemical and morphological surface properties. Membrane bioartificial organs are engineered to be used as extracorporeal devices or implantable systems. These devices can be distinguished on the basis of membrane material configuration, molecular weight cutoff or pore size, and cell culture technique. Cells can be compartmentalized in the lumen or shell of hollow fiber membranes (HFMs) or between flat-sheet membranes, in a network of HF membranes, spirally wound module, encapsulated or attached to microcarriers.

The most common membranes used in the membrane bioartificial organs are hydrophilic membranes with molecular weight cutoff ranging from 20,000 to 120,000 daltons, which are chosen on the basis of the molecules that have to provide to the cells and removed from them. The creation of a physiological environment requires the use of membranes with specific physicochemical, morphological, and transport properties on the basis of the targeted tissue or organ (De Bartolo et al. 2012).

Membrane Biocompatibility

Loredana De Bartolo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

Biocompatibility of membranes

Membrane biocompatibility is the ability of membrane to perform its intended function without eliciting any host undesirable local or systemic effects. Membrane biocompatibility is a general term that must be subcategorized on the basis of the membrane applications in order to be able to make more narrow definitions. In the case of membranes used in the hemodialyzers, hemofilters, hemodiafilters, and blood oxygenator, the more appropriate term is blood compatibility or hemocompatibility because of the main interactions between membrane and blood. When blood comes into contact with an artificial surface, protein adsorption occurs in the first seconds. Proteins like albumin, immunoglobulin G, fibrinogen, fibronectin, factor XII, and high molecular weight kininogen are adsorbed forming a layer that supports the platelet adherence. The adsorption of thrombin may activate the clotting cascade

(Ulhenbusch et al. 2004). The protein adsorption process is strongly dependent on the physico-chemical (e.g., surface charge, functional groups) and morphological (e.g., porosity, roughness) surface properties of the membranes (De Bartolo et al. 2004). On the other hand, the artificial surface may activate the complement cascade through the membrane-bound complement factors such as C3b and iC3b. After the protein adhesion, platelet changes their morphology, release factors, and aggregate. The adsorbed proteins activate also the coagulation cascade with the fibrin and thrombus formation, which occur within several minutes. The coagulation pathway consists of a series of reactions, each requiring the formation of a surface-bound enzyme complex. In these reactions, inactive precursor proteins are transformed into active protease.

Several studies indicated that platelet activation increases in the positively charged membrane and decreases in the membrane having a microdomain structure in which hydrophilic and hydrophobic groups coexist randomly as molecules. Also, the complement activation, which in the case of biomaterials proceeds via alternative pathway, is mainly noted with cellulose membranes; free hydroxyl groups on the membrane surface are bonded with C3b and further with factor B that promotes the activation. Improvements of biocompatibility of cellulose membrane can be obtained by surface modification devoted to graft, for example, alkyl group to the hydroxyl group.

When membranes are used in bioartificial systems (bioartificial organs and tissues), it is important to consider the cytocompatibility of membrane on which depends the response of the biological components. In bioartificial systems, cells come into contact with the membrane surface. Therefore, their morphological and functional response depends on the surface and transport membrane properties. Physicochemical properties, including surface composition, charge, energy, and morphology, may affect cell adhesion and behavior. In vivo cells are surrounded by the extracellular matrix (ECM) that provides physical architecture and mechanical strength to the tissue.

The native ECM exhibits from macro- to nanoscale patterns of chemistry and topography. For this reason, the cells can respond to various chemically and/or topographically patterned features. When cells are cultured in vitro, they receive very different physical, chemical, and mechanical stimuli from the unfamiliar surrounding environment. Micro- and nanoscale mechanical properties of the membranes are critical because the cells not only adhere to the surface but also pull on the surface substrate and on adjacent cells. The surface chemistry of the membrane affects the adhesion of cells through the ECM protein adsorption and stereospecific chemical interactions. Several approaches have been undertaken to improve the cytocompatibility of membranes by increasing the wettability or by surface modification through grafting of functional groups or immobilization of peptides, and proteins, which interact with the cell receptors (De Bartolo et al. 2005, 2006, Salerno et al. 2009). It is known that the cytocompatibility of the membrane can be increased by modulating its surface free energy and roughness (De Bartolo et al. 2002). It has been shown a significant enhancement of the hepatocyte adhesion and metabolic functions on membrane with high value of surface free energy base parameters.

Membrane Biomaterial

Loredana De Bartolo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane biomaterial is any material constituted of membrane that is in contact with biological fluids, organs, tissues, and cells (Williams 2009). Membranes are used as components of medical devices and implants, drug delivery systems, diagnostic assays, and bioreactor and bioseparation processes. They are employed in the replacement therapy for acute and chronic organ failure and in the management of immunological disease as well as in the tissue engineering for the realization of tissue-engineered constructs and defined models supporting investigations on cell function, tissue development, and drug testing. In many clinical therapeutic blood processes are used membrane devices for the removal of endogenous or exogenous toxins from blood (hemodialysis, hemofiltration, hemodiafiltration, plasmapheresis) or for the gas exchange with blood (blood oxygenation) (De Bartolo and Drioli 1998). Membranes of suitable molecular weight

cutoff are used in bioartificial organs (e.g., the pancreas, liver) for compartmentalization of cells and as selective barriers to prevent immune system components from getting into contact with the implant while allowing nutrients and metabolites to permeate freely to and from cells. Membrane-based biomaterials can be realized with different properties on the basis of the functions to be performed. Membranes can be porous or dense, hydrophilic or hydrophobic, natural or synthetic, biodegradable or not biodegradable, and stiff or elastic. However, all membranes properties play an important role in the interactions with cells or biological fluids. Physicochemical properties, morphology, roughness, permeability, and mechanical characteristics affect the biological response and consequentially the performance of the membrane. As a result, the biocompatibility and cytocompatibility of the membrane biomaterial are dependent on its properties related to the application in cells, tissues, organs, and blood. To meet the needs of the biomedical requirements, membranes have to be compatible with biological systems performing their function with an appropriate host response (Ratner et al. 2012). The interactions may involve, for example, platelet aggregation and blood coagulation in the case of blood-contacting devices, immune response, and foreign body reactions when the membrane biomaterials or devices are implanted in the body. The interactions with cells may involve a structural and functional connection or may lead to the cell death and nonviable tissue-engineered constructs.

The most common synthetic membranes used in biomedical applications are made of cellulose acetate (CA), nitrocellulose (CN), and cellulose esters (CE), polysulfone (PS), polyethersulfone (PES), polyacrylonitrile (PAN), polyamide (PA), polyimide (PI), polyethylene (PE), polypropylene (PP), polytetrafluoroethylene (PTFE), polyvinylidene fluoride (PVDF), polyarylethersulfones (PAES), polyvinyl chloride (PVC), ethylene vinyl alcohol (EVAL), polyethyleneimine (PEI), and polymethyl methacrylate (PMMA) (Baker 2004). These membranes are used extracorporeally connected to the patient's body

through blood circulation as, for example, in hemodialysis, hemodiafiltration, blood oxygenation, and bioartificial organs.

In tissue engineering or in implants are used mainly biodegradable membranes that undergo hydrolytic or enzymatic degradation. These membranes are mainly made of polyglycolide or poly(glycolic acid) (PGA), polylactide (PLA), poly(lactic-co-glycolic acid) (PLGA), polycaprolactone (PCL), polycarbonate (PC), polyurethanes (PU), polyphosphazenes (PPHOS), polyamide (PA), chitosan (CHT), hyaluronic acid (HA), collagen, and poly(p-dioxanone) (PDO). Biodegradable membrane biomaterials can be implanted in situ into the body. An example is the commercial collagen resorbable membrane from highly purified type I collagen that is used for repairing tears and wound healing. Specifically, membrane biomaterials that are biodegradable provide the significant advantage of being able to be broken down and removed after they have served their function (De Bartolo and Bader 2013).

Responsive membranes are used in the area of cell sheet engineering for the in vitro tissue reconstruction. These membranes allow the adhesion and proliferation of cells at a temperature above the lower critical solution temperature of the grafted polymer (a state where in the surface is hydrophobic) and the detachment of cells when the temperature is lowered below the lower critical solution, because of spontaneous hydration of the grafted polymer chains.

Nowadays, decentralized wastewater treatment system (WWTS) becomes interested treatment technology in many countries. To catch up the wastewater treatment requirement, there are many decentralized biological wastewater treatment technologies used such as conventional activated sludge process, trickling filter, oxidation ditch, rotating biological contactor, etc. Besides, these technologies seem to be appropriate only to the available construction area (Günder and Krauth 1999). The MBR technologies have evolved drastically in the recent period, and the technology proves many advantages in considerably reducing the foot-print requirement to treat a given flow, increasing the volumetric loading rate, augmenting the effluent quality (Lobos et al. 2007; Thanh et al. 2008), and trimming down the chemical requirements for disinfection.

The initial development of MBR technology began in the late 1960s, which is the platform of

Membrane Bioreactor for Decentralized Wastewater Treatment: A Case Study,

Fig. 1 Small and limited parking lot at Caravelle Hotel

rapid growth in the early 1990s (Stephenson et al. 2000). Presently, MBR application becomes popular around the world owing to many striking advantages. Some hotels are among pioneers of MBR technology application in WWTS.

A case study of a renowned hotel in Ho Chi Min City is here reported. Total wastewater generated mainly from hotel operation with capacity of 350 m³/day includes sources from toilets, lavaboes, kitchens, food courts, and restaurants. Before 2010, there was only one three-chamber septic tank for treating entire wastewater in the hotel, which cannot comply with the new environmental regulation. The regulation is changing day by day and becomes stricter with treated wastewater discharging to the environment – QCVN 14:2008/BTNMT. Consequently, it is really essential to have upgraded WWTS coupling with the existing septic tank in the hotel so as to improve the treated water quality not only to meet the new current regulation but also to reuse treated water for many purposes. Nevertheless, modification plan of WWTS is not included in the initial construction plan of the hotel managers which leads to limited construction space for the new system. Many implemented surveys show that only parking lot at the basement can be the only place for new WWTS. After weighing the pros and cons of many proposed technologies, the MBR technology seems to be

the proper choice in this case instead of the conventional activated sludge process which requires large area for sedimentation and disinfection tank. Because of 70 % of space saving, membrane system becomes smart and appropriate choice for such small parking lot at basement of the hotel (Fig. 1).

Membrane Bioreactor Technology: Decentralized WWTS for Caravelle Hotel

Wastewater generated from Caravelle Hotel is gathered and contained in the existing septic tank for pretreatment before being pumped into equalization tank later using two submersible pumps. The equalization tank is responsible for regulating flow rate as well as pollutant concentrations in wastewater to avoid overloading for later unit processes. Wastewater is then pumped into anoxic tank and aeration tank (called A/O process) in order to achieve degradation of organic matters, nitrification, and denitrification process. Compressed air is supplied continuously to aeration tank using two air blowers and diffuser system to maintain the stable growth and development of microorganism. Membrane modules were inserted into the second chamber of the aeration tank. With the pore size of 0.4 µm hollow fiber membrane, most of the sludge particles and

microorganisms such as *E. coli* and coliforms are retained inside the aeration tank and eliminated out off the membrane permeate. The membrane characteristics are summarized in Table 1 and the process diagram of WWTS is demonstrated in Fig. 2 (Table 2).

Table 3 shows that all required parameters such as BOD, ammonia nitrogen, nitrate nitrogen, and total coliforms comply with Viet Nam national technical regulation – level A, QCVN 14:2008/ BTNMT after long-term operation. Especially, turbidity removal reaches maximum value of 98–100 %. The superior results show the excellent application of MBR technology in Caravelle Hotel.

Another special benefit of MBR technology which cannot help to be mentioned is reusing ability of treated wastewater after MBR treatment for many purposes such as toilet flushing, floor washing, watering, or cooling water for central air conditioning system in the hotel. Notwithstanding, tea like color appearing in treated

MBR permeate. After additional treatment step, treated wastewater can be reused inside the hotel as per the abovementioned activities. Total amount of reusable water can be estimated approximately of 180 cubic meter per day compared to total wastewater generated with capacity of 350 cubic meter per day.

By and large, MBR technology becomes potential and attractive application not only in Viet Nam but also all over the world in the near future. Notwithstanding, there are still issues in MBR system operation, especially specific problems relating to MBR such as membrane fouling which need further researches to be perfect. Despite some disadvantages, MBR technology will be always considered as an optimal treatment solution because of high treated effluent, space saving, automatic operation, and easy maintenance; especially for limited foot-print area like Caravelle Hotel. The MBR technology gradually becomes dominant technology in the urban cities of Viet Nam.

Membrane Bioreactor Using Extremophiles

Chiara Schiraldi and Mario De Rosa
Department of Experimental Medicine, Section of Biotechnology, Medical Histology and Molecular Biology, Second University of Naples, Napoli, Italy

Membrane bioreactors are apparatuses, like stirred tank reactors, traditional fermentation vessels, or tubular reactors, that are implemented with additional separation devices based on membrane modules to permit the medium exchange at request during bioprocessing. Membrane bioreactors have been exploited in the cultivation of demanding organisms, such as extremophiles, or

in order to meet productivity target in pilot scale or even industrial-scale biotechnological production processes. Extremophiles are peculiar microorganisms that can grow and thrive in extreme environments, which were formerly considered too hostile to support life. They are structurally adapted at the molecular level to withstand at least one of the following harsh conditions: very high (hyperthermophiles) or low temperature, high or low pH, high salinity (halophiles), high metal/organic compound concentrations, high pressure, and low oxygen tension. A few of them proved resistant to multiple stress conditions. The biocatalysts, called extremozymes, produced by these microorganisms, are proteins adapted to function under these extreme conditions. Due to their outstanding stability, extremozymes have great potential for application in various biotechnological processes. Notwithstanding this natural resource and the remarkable opportunities that these uncommon organisms present for biotechnological applications, only few have been commercially exploited because of the difficulties encountered in attempting their cultivation. Hence, special equipment and custom-tailored processes have been developed and are currently under evaluation for the improvement of fermentation productivity. Specific fermentation apparatuses have been employed in the extremophilic biomass and related product production with sound results at a laboratory scale. The pioneering dialysis bioreactor was designed by the biotechnology group at the Technical University of Harburg-Hamburg (Krahe et al. 1996), developed and constructed by bioengineering at 1 and 5 L scale. The dialysis fermenter was used in the cultivation of the hyperthermophile *Pyrococcus furiosus*, the thermoacidophile *Sulfolobus shibatae*, and the halophile *Marinococcus* M52 resulting in high cell yields up to 40-fold with respect to the corresponding batch experiments. The main idea was to assure the removal of (unknown) toxic compound while sustaining growth through appropriate nutrient feeding. On the lab scale, this was achieved through a massive external dialyses, generating wastewater but assuring an efficient increase in biomass final density. A similar approach, based on

Membrane Bioreactor Using Extremophiles,

Fig. 1 Microfiltration modules fixed to the baffles of a 15 L fermenter

microfiltration (pressure-driven exchange rate) in place of dialysis, was developed by Prof. De Rosa's group (Schiraldi et al. 1999, 2001). The specific microfiltration modules (Fig. 1), tailor made, biocompatible, and resistant to the harsh cultivation condition, were assembled at the Second University of Naples; also the bioreactor vessel (Sartorius Stedim, BBI, Germany) was modified with module insertion next to the baffles and investigated for improving efficiency of extremophilic biomasses and enzyme production. In spite of the difficulties in cultivating hyperthermophiles (70–80 °C, pH 3.5), adopting a specifically developed nutrient-split feeding strategy, in 300 h fermentation, more than 30-fold biomass dry weight increase was achieved for *Sulfolobus solfataricus*, and the activity of the constitutive enzyme alcohol dehydrogenase (ADH) was not affected by cell density. Modifying the cultivation condition and the medium exchange rate, the MF fermentation strategy proved effective in the production of compatible solutes from *Marinococcus* M52 (Schiraldi et al. 2006). Membrane bioreactors proved effective in enhancing final cell densities in hyperthermophile, acidophile, and halophile cultivations. However, a recent review of Alain and Querellou (2009) suggests that the main hindrance to extremophile cultivation is likely due to the prevailing lack of knowledge on targeted species. These scientists focus on the limiting factors surrounding cultivation also discussing potential issues including the loss of

microbial cell-cell communication following species isolation and finally suggesting future research directions.

- Membrane bioreactors is the general term indicating a membrane reactor using a catalyst of biological origin. Similar terms commonly used include “biochemical membrane reactors,” “biological membrane reactors,” “membrane fermentors,” “biocatalytic membrane reactors,” and “enzyme membrane reactors.” Table 1 summarizes the most common biocatalysts used as well as the role played by the membrane (Drioli and Giorno 2010; Mazzei et al. 2013). Most membrane operations have been used as separation process in membrane bioreactors, including pressure-driven membrane processes, membrane-based solvent extraction, membrane contactors, electrodialysis, and forward osmosis.

In general, the membrane can work simply as a separation unit, or it can function also as a support for the biocatalyst (in this case biohybrid systems are obtained and the reactor is more appropriately termed “biocatalytic membrane reactor,” meaning that the membrane has catalytic properties). In the first case, the reaction occurs in a tank connected to a membrane module where the separation occurs. The reaction and transport rate can be governed independently. The membrane has an indirect effect on the reaction by controlling the mass transport in and out of the reaction environment, i.e., removing products, adding reagents, and retaining the catalyst in the reaction bulk phase. The membrane module can be placed externally to the tank (side-stream configuration) or it can be immersed into the tank (submerged configuration) (Fig. 1; Judd, 2010).

In the biocatalytic membrane reactor, the reaction occurs at the membrane level. The transport rate may influence the reaction performance. The membrane has both a direct effect on the reaction and governs the mass transport through the reaction environment.

Figure 2 illustrates the general classification of various biochemical membrane reactors. Here, schematics represent the external or side-stream configuration, in which case the membrane modules are outside the bioreactor and solution is recirculated through a membrane separation loop (Drioli and Giorno 1999, 2000; Mazzei 2010). However, also submerged (or immersed) membrane configuration can be used.

Membrane Bioreactors, Table 1 Biocatalysts used in biological membrane reactors

Biocatalyst	Status	Common membrane role	Reaction components properties
Enzymes	Compartmentalized	Enzyme recycle, product separation, and/or reagent supply	Enzymes need cofactors, substrates are large polymers, reaction mixture is very viscous
	Immobilized on membrane surface	Support for the catalyst	The size of the substrate is too big to enter the membrane matrix, products can pass through the membrane
	Immobilized within the membrane matrix	Support for the catalyst, reagent supply, product separation	The size of the substrate and products is suitable to be transported through the membrane
Bacteria cells	Compartmentalized	Cell recycle, products and/or purified components separation, and/or reagent supply	Cells operate the transformation of interest during the growing phase of the fermentation
	Immobilized	Support for the catalyst, reagent supply, product separation	Cells can operate the transformation of interest during a phase different than the growing one
Fungi	Compartmentalized and/or attached on the membrane surface	Biocatalyst recycle, components separation	Biocatalyst grows in the bulk phase and/or it needs to attach on a surface to form a biofilm
Yeast			
Virus			
Algae/microalgae		Biocatalyst growth	
Mammalian cells	Compartmentalized	Cell recycle, metabolites supply, catabolites removal	Cells, such as red cell blood, lymphocytes, leucocytes, need to be maintained alive in bulk phase
	Attached	Support for cell growth, metabolites supply, catabolites removal	Cells anchorage dependent, such as hepatocytes, neurons, epithelia, need to adhere to surface for the differentiation and biotransformation

Membrane bioreactors have several intrinsic advantages, including small footprint, continuous operation, biocatalyst reuse, selective supply of substrate, selective removal of the product (thus limiting product inhibition phenomena in addition to maximizing substrate conversion by shifting the reaction equilibrium to the right on the basis of the Le Chatelier principle), and possibility to carry out simultaneously reaction and separation.

Among the various types of biochemical membrane reactors, the submerged bioreactors are the most used on a large industrial scale. Their concept was conceived in the late 1980s/early 1990s by independent teams in Japan and Canada. They are mostly applied for waste water treatment, even though some investigation for bioreaction is also available. Microorganisms (including bacteria, yeast, fungi, algae) are mainly used as biocatalysts. They are the most recent type of bioreactor conceived; nevertheless they are the

most mature process among the biochemical membrane bioreactors (Fig. 3). Figure 3 illustrates the behavior of a technology performance as a function of research effort and the related location of most common biochemical membrane reactors. It can be seen that significant research efforts have been invested in this technology that rapidly advanced it to a mature stage (Fig. 3).

They are recognized by the directive of the European Commission “The Integrated Pollution Prevention and Control (IPPC) Directive (1996)” among the best available technologies (BAT) for waste water treatment

The external (side stream) membrane bioreactor, using the membrane as a separation unit, is applied in many bioprocessing, in particular in food, biotechnology, pharmaceutical, and biomedical fields. Nowadays, their investigation in the area of biorefining is attracting much attention. Both microorganisms and enzymes are used

Membrane Bioreactors,**Fig. 1** Membrane configuration module (a) Side-stream and (b) submerged configuration**Membrane Bioreactors, Fig. 2** Schematic classification of biochemical membrane reactors (the side stream configuration of the module is reported, but submerged membrane can also be used)

Membrane Bioreactors, Fig. 3 Development stage of various biochemical membrane reactors. (Drioli and Giorno 2010)

as biocatalysts. This type of bioreactor is at a developing stage approaching the mature service stage (Fig. 3).

The biocatalytic membrane reactors, using biocatalyst-loaded membranes, are mainly used as side-stream configuration and are mostly applied in pharmaceutical, biotechnology, and food production. Some examples of submerged biocatalytic membranes have been investigated for water decontamination, biodiesel production, and control of fouling. Even though some bacteria in vegetative stage have been immobilized in membranes, enzymes are the widely used biocatalysts in this type of bioreactor.

As illustrated in Fig. 2, the enzyme can be loaded on the membrane surface or within the porous matrix. It can be entrapped within the porous matrix during the membrane formation by phase inversion promoted by non-solvent-induced phase separation (NIP), or it can be entrapped by cross-flow filtration in already formed membranes. The enzyme can be mechanically entrapped (on the basis of the higher molecular size compared to the pore size of the membrane matrix), physically gelled on the surface of porous membrane (during ultrafiltration the enzyme is retained on the membrane surface

while the solvent is permeated through the membrane; the enzyme is concentrated at the interface up to the precipitation value, forming a gel cake layer of enzyme), or can be chemically bound to the membrane surface and/or porous matrix. Chemical bond includes physical adsorption, ionic binding, covalent bond, and cross-linking.

Despite the large variety of enzymes immobilized in membranes, their investigation for numerous bioconversions, and the great potential they offer for a clean, safe, intensified, and sustainable production, their development is still at an emerging stage (Fig. 3) with research effort limited on a lab scale. The need for highly selective processes able to reduce wastes and by-products may help to change the trend.

Membrane Bioreactors for Cell Growth

Loredana De Bartolo

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane bioreactors composed of semipermeable membranes and bioreactors are very attractive for the culture of animal, plant, and microbial cells. For mammalian cell cultures, membrane bioreactors are mainly used to produce biochemicals such as vaccines, interferons, hormones, growth factors, viruses, and monoclonal antibodies and to act as artificial organs. More recently, membrane bioreactors found applications in the area of regenerative medicine for developing functional tissues from cells in combination with a suitable matrix to support and accelerate regenerative healing. In these devices, usually cells are immobilized in a compartment separate from the feed medium containing nutrients that diffuse through the membrane to the cell compartment. Membrane with suitable MWCO allows the retention of cells and the separation of cell products from the feeding stream. Multiple functions are performed by membrane in the bioreactor: (i) compartmentalization of cells, (ii) the selective transport of nutrients and metabolites to

the cells and the removal of catabolites and cell products, (iii) wide surface for adhesion of anchorage-dependent cells, and (iv) protection of cells from shear stress. The efficiency of the overall system depends on the cells (viability, functions, density), membranes (configuration, structure, size, morphology, pore size distribution, physicochemical and mechanical properties), and hydrodynamic parameters (flow rate, transmembrane pressure, residence time, shear stress, etc.). A critical point in the design of an efficient membrane bioreactor for cell growth is the overall transmembrane mass flux of metabolites, catabolites, cell regulatory, and related soluble factors that need to be considered. Molecules contained in the culture medium, which are fed and produced by cells, are comprised on a wide range of molecular sizes (from small electrolytes to large proteins) and physicochemical properties (hydrophilic, hydrophobic molecules). The transport of low MW nutrients and metabolites is assumed to occur by diffusion, whereas convection phenomena are supposed to regulate the mass transfer of macromolecular species and proteins (Giorno et al. 2011). Surface properties of membranes need to be also considered in the design of a membrane bioreactor for the culture and expansion of adherent cells that are in tight contact with the membrane surface. Membranes should have surface characteristics in terms of morphology and physicochemical and mechanical properties that favor the adhesion process and the integration of cells. Membrane bioreactors have been investigated for the culture of lymphocytes, liver cells, embryonic stem cells, progenitor cells, and stem cells. These devices have been used in replacement therapy for acute and chronic organ failure and in the management of immunological disease as well as in tissue engineering for the realization of tissue-engineered constructs and defined models supporting investigations on cell function, tissue development, and drug testing. Different configurations of membrane bioreactor have been explored for the culture and growth of mammalian cells. Primary cells, immortalized cells, and stem cells can be cultured (a) on flat-sheet membranes, (b) in the lumen or shell of hollow

fiber membranes in suspension or attached to the membrane surface, (c) in a network of hollow fiber membranes, (d) in a spirally wound membrane device, (e) in multibore fibers, and (f) in gas-permeable membrane bioreactor. Flat membrane bioreactor is a simple device that has been developed for the small-scale culture of cells (e.g., neurons, hepatocytes) as tool for drug screening and toxicological studies (De Bartolo et al. 2006a). In this device a microporous flat-sheet membrane separates the medium compartment from the cells that are adhered on the membrane. Advanced bioreactors use additionally gas-permeable membranes (e.g., fluorocarbon membranes), which are permeable to oxygen, carbon dioxide, and water vapor, in order to improve the oxygenation of cells. In this device cells receive oxygen directly from the bottom membrane sheet where they are seeded and indirectly from the microporous membrane in contact with the medium overlaying the cells (De Bartolo et al. 2006b). Hollow fiber membrane bioreactors are the most used bioreactors for high cell density culture. In these devices cells usually are cultured in the shell of a bundle of hollow fiber membranes parallel-assembled, and the medium flows in the lumen (De Bartolo et al. 2007b). Alternatively cells can be cultured inside the lumen of hollow fiber and the medium flows in the shell (Demetriou et al. 1986). In both cases the medium and cell compartments communicate through the pores of the fiber wall. Advanced designs of bioreactors using a network of hollow fiber membranes with different properties have been developed for the culture of cells in order to improve the mass transfer (Gerlach et al. 1994). Spirally wound bioreactor has been proposed for the culture of hepatocytes and other mammalian cells. This bioreactor consists of spiral-wound membranes, and some devices include also a layer of polypropylene hollow fiber membranes for cell oxygenation (Flendrig et al. 1997). Bioreactors using multibore capillaries have been developed in the last years for the culture of human hepatocytes (De Bartolo et al. 2007a). This device is composed of multibore membranes of modified poly(ethersulfone) constituted of

seven compartments represented by seven capillaries arranged in one single fiber. The seven compartments communicate through a porous foamy support structure that is located in between the capillaries. In this bioreactor human hepatocytes have been cultured inside the lumen of the multibore fibers and lumen in the shell compartment. In the last years membrane bioreactors have been developed for the expansion and transdifferentiation of stem cells to be used in cell therapy and tissue engineering applications (Salerno et al. 2013).

Membrane Bioreactors for Treatment of Tannery Effluents

Zhiwei Wang

Department of Environmental Engineering,
College of Environmental Science and
Engineering, Tongji University, Shanghai, China

Synonyms

Industrial/tannery wastewater treatment using
membrane bioreactors

Introduction

The tanning process aims to treat animal raw skins to produce leather, which is more durable and less susceptible to decomposition. The whole process includes several procedures as shown in Fig. 1: beamhouse operation, tanyard processes, retanning, and finishing (Tunay et al. 1995; Cooman et al. 2003; Lofrano et al. 2013). In general, tanning can be performed with either vegetable or mineral methods. However, the mineral method (e.g., chrome tanning) is faster than vegetable tanning (less than a day for this part of the process) and produces a stretchable leather which is excellent for use in handbags and garments.

The wastewater amount generated from tannery industry is in a wide range (10–100 m³ per

ton hide) dependent on the raw material, the finishing product, and the production processes (Tunay et al. 1995). Characteristics of tannery wastewater are summarized as follows: pH 6–11; chemical oxygen demand (COD), 2100–11,000 mg/L; biochemical oxygen demand (BOD₅), 100–2900 mg/L; total suspended solids (TSS), 500–2900 mg/L; total dissolved solids (TDS), 6800–37,000 mg/L; alkalinity, 600–1000 mg/L; sulfide, 30–900 mg/L; ammonia, 30–350 mg/L; and chromium, 10–260 mg/L (Lofrano et al. 2013). In general, tannery wastewaters include high organic concentration, high salt content, and various inhibitory compounds, which must be properly treated.

Membrane bioreactor (MBR) processes, which use membrane filtration units to replace the secondary clarifier, offer several prominent advantages over the conventional activated sludge processes, such as improved effluent quality, higher volumetric organic load, reduced footprint, and less sludge production (Wang et al. 2008; Judd 2011). MBR can be operated under longer sludge retention time (SRT), which facilitates the growth of microbes that have long generation time. This will enhance the pollutant removal efficiency due to the presence of those microbes that may be absent in conventional activated sludge (CAS) processes. For instance, the slow-growing nitrifying bacteria can be enriched in MBRs, leading to the improved nitrification efficiency (Lin et al. 2012). The high biomass concentration maintained in MBRs also contributes to the enhanced degradation of recalcitrant organic

Membrane Bioreactors for Treatment of Tannery Effluents, Fig. 1 Unit processes in leather production

matters since the dominant bacteria and microbial community diversity might be increased compared to CAS systems (Ma et al. 2013). Therefore, the use of MBR for tannery wastewater treatment can achieve relatively better effluent quality compared to CAS systems. The COD and ammonia removal efficiencies are usually more than 90 % in MBRs with proper design and operation (Lin et al. 2012). In terms of heavy metal (e.g., chromium) treatment, the combination of MBR process and low-cost additives can effectively remove chromium (Malamis et al. 2009).

As for the design of MBR for tannery wastewater treatment, both submerged and external MBR configuration can be adopted. Membrane modules including hollow fiber, tubular, and flat sheet modules can be used. In general, hydraulic retention time (HRT) varies from 0.33 to 4.16 days, while solid retention time (SRT) is usually in the range of 5–150 day (Lin et al. 2012). The combination of anaerobic pretreatment (e.g., upflow anaerobic sludge blanket) with MBR is recommended.

Membrane Bioreactors with Biocatalyst Segregated in the Membrane Module

Lidietta Giorno and Rosalinda Mazzei
Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In these reactors, enzymes or cells are not linked but only confined in a defined region of membrane module space. The segregation of the biocatalyst is achieved by means of membranes with a suitable molecular weight cutoff. In this way, enzymes and bacterial cells are not lost in the effluent stream, and low-molecular weight products and inhibitors can be removed through the membrane (Fig. 1). The development of hollow fibers with diameters down to about 100 μm makes possible tube-and-shell reactors with a high surface-to-volume ratio.

Membrane can segregate enzymes or cells either within the hollow fiber lumen or within the shell surrounding the outer surface of the fibers. Figure 2 shows the case where the biocatalyst is segregated within the lumen of capillary membrane, which separates the product of the bioconversion.

The case where the biocatalysts are present within the porous membrane support are more appropriately said “biocatalysts entrapped” rather than “segregated,” to account for the more reduced space around the biocatalyst. There is growing interest in therapeutic applications of compartmentalized cells or microsomes

Membrane Bioreactors with Biocatalyst Segregated in the Membrane Module, Fig. 1 Schematic of a membrane module with capillary membrane module

Membrane Bioreactors with Biocatalyst Segregated in the Membrane Module,

Fig. 2 Membrane module with biocatalyst segregated within the lumen of capillary membrane

Membrane Bioreactors with Biocatalyst Segregated in the Membrane Module, Table 1 Most common application of membrane bioreactors with segregated biocatalyst

Bioconversion (biocatalyst)	Membrane bioreactor	Application
Insulin secretion (Langerhans islets)	Polyamide capillary membrane (pore size: 10–100 nm)	Bioartificial pancreas
Liver metabolism (hepatocytes)	Polysulfone capillary membrane (pore size: 10–100 nm)	Bioartificial liver
Cellular metabolism (cancerogenic cells)	Polysulfone capillary membrane (pore size: 0.1–1 μm)	Study of cancerogenic cell growth/differentiation

functioning as a bioartificial pancreas or extracorporeal detoxification device (Goosen et al. 1985; Takabakate et al. 1991). Evaluation of stability and catalytic properties of the immobilized system must take into account possible pH differences between the inner core of the fiber, where the reaction takes place, and the bulk of the feed solution.

The most common application of membrane bioreactor with cells segregated at the level of the membrane module (lumen or shell) is summarized in Table 1.

Membrane processes play a key role in modern therapy for treating acute and chronic organ failure and in the management of immunologic diseases. In fact, membrane devices are employed in most extracorporeal blood purification methods, and the next generation of artificial organs and tissue engineering therapies is likely to be grounded on membrane technology. Intracorporeal uses of membrane devices include contact lens, biosensors, drug delivery systems, and artificial grafts.

The use of membrane bioreactors in the development of new artificial organs is attracting today significant attention. Over 20 million patients are sustained by functional organ replacement. Most of recent research activity has been focused on organ replacement and extracorporeal treatment. Two main strategies are followed: (i) the use of membrane as toxins separator and (ii) the use of cells combined with membrane to remove toxins and supply metabolic organ functions. Membrane bioartificial pancreas using isolated islets of Langerhans segregated by membranes represent an alternative approach to the transplantation of the whole pancreas in patients with insulin-dependent diabetes. Various investigations are directed to protect cells from immunorejection, to maintain the cell viability and functions, to reduce diffusion resistance of nutrients and metabolites, and to study the kinetics of transformation of glucose into insulin.

Membrane Bioreactors with Membrane Used as a Separation Unit

Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

This type of membrane reactor is based on the combination of a continuously stirred tank reactor (CSTR) with a membrane separation process (Fig. 1). The membrane simply acts as a separation unit and does not take part directly to the reaction. The reactor works as a CSTR, but the product passes through the membrane unit where the enzyme is retained and recycled back into the reactor or remains confined in the membrane module.

An appropriate membrane separation is used to keep larger components in the reaction vessel (i.e., enzyme and macromolecular substrates) and remove low-molecular-weight molecules (i.e., product, inhibitor). The biocatalyst is immobilized by the fact that it is compartmentalized by the membrane in the reaction vessel. This allows continuous processing with the biocatalyst suspended in a homogeneous solution. Direct contact between the substrate and biocatalyst limits diffusional resistance.

The most common separation process used in this kind of setup is ultrafiltration (Table 1).

Membrane Bioreactors with Membrane Used as a Separation Unit,

Fig. 1 Membrane bioreactors with inert membrane serving as a separation unit

Dead-end and continuous stirred ultrafiltration cells with flat membranes have been widely used; furthermore, cross-flow ultrafiltration through tubular membrane modules has been investigated.

Concentration polarization phenomena severely affect the performance of reactors where the membrane is used only as a separation media, and then it is necessary to control the polarization layer on the membrane-pressurized side by means of reactor fluid dynamics or appropriate design. Fluid dynamic conditions in some of these reactors make them especially suitable for enzymatic systems for which a homogeneous catalyst distribution is particularly important, such as cofactor-requiring mono- and multienzyme systems.

Enzyme activity is usually not constant with time. Physical chemical changes in enzyme structure, thermal denaturation, and microbial contamination cause enzyme activity to continuously decrease with time. When enzymes or cells are compartmentalized in UF cells, biocatalyst losses can even occur due to the wrong choice of chemical properties and morphology of the membrane.

It is conventional to measure the enzyme stability in terms of its half-life time ($t_{1/2}$); that is the time at which enzyme activity is reduced to half its initial value. It can be calculated from the following equations:

$$t_{1/2} = \frac{0.693}{K_d} \quad (1)$$

$$K_d = \frac{2.303}{\vartheta} \log \frac{A_{E_0}}{A_{E_\vartheta}} \quad (2)$$

K_d is the enzyme deactivation constant; ϑ is the operation time; A_{E_0} is the initial enzyme activity or product mass per unit time and reaction volume; A_{E_ϑ} is the enzyme activity at time ϑ .

Since biotransformations by means of enzymes are continuous processes, as long as the reactor working life is longer than the native enzyme half-life, enzyme activity decay with time must be taken into account in order to correctly assess reactor performance.

The CSTR/UF reactor is useful for several types of reactions where a typical immobilized enzyme would not be effective.

Membrane Bioreactors with Membrane Used as a Separation Unit, Table 1 Most common membrane processes combined with reactions

Process	Driving force	Mode of transport	Species passed	Species retained
Microfiltration (MF)	Pressure difference	Size exclusion convection	Solvent (water) and dissolved solutes	Suspended solids, fine particulars, some colloids
	100–500 kPa			
Ultrafiltration (UF)	Pressure difference	Size exclusion convection	Solvent (water) and low-molecular-weight solutes (<1,000 Da)	Macrosolutes and colloids
	100–800 kPa			
Nanofiltration (NF)	Pressure difference	Size exclusion	Solvent (water), low-molecular-weight solutes, monovalent ions	Molecular weight compounds >200 Da multivalent ions
	chemical potential	Solution-diffusion		
		Donnan exclusion		
Forward osmosis (FO)	Concentration gradient	Solution-diffusion	Solvent (water)	Molecules, ions
	chemical potential			
Membrane distillation (MD)	Temperature gradient	Evaporation through nonwetting porous matrix	Vapor phase	Liquid phase
	vapor tension difference			
Membrane-based solvent extraction (MBSX)	Chemical potential or concentration difference	Diffusion partition	Compounds soluble in the extraction solvent	Compounds nonsoluble in the extraction solvent
Gas separation (GS)	Pressure difference	Solution-diffusion mechanism	Gas molecules having low molecular weight or high solubility-diffusivity	Gas molecules having high molecular weight or low solubility-diffusivity
	0.1–10 MPa			
Pervaporation (PV)	Chemical potential or concentration difference	Solution-diffusion mechanism	High permeable solute or solvents	Less permeable solute or solvents

Membrane Biosorption

A. B. Koltuniewicz

Biotechnology and Bioprocess Engineering Division, Faculty of Chemical and Process Engineering, Warsaw University of Technology, Warsaw, Poland

Biosorption, in the biological sense, is the ability of cells (usually microorganisms) to bind various substances in a passive way. Bioaccumulation of cells is the active retrieval from the environment

of certain components needed for life (i.e., metabolism). Biosorption can be achieved through a variety of specific mechanisms, where physical adsorption, ion exchange, and chemical reactions play a dominant role. Table 1 (below) shows the sorption capacity of various microorganisms such as bacteria, fungi, and algae.

Biosorption is also a new separation process (Volesky 1990) which depends on the concentration, temperature, pH, and sorbent properties that determine the equilibrium and kinetics. Cell debris may be also regarded as sorbents, which have even better sorption properties than whole cells because of greater sorption capacity (see

Membrane Biosorption, Table 1 Maximum uptake of heavy metals on various microorganisms

Type of biosorbent (microorganisms)	Heavy metal	Maximum uptake q^* (mg metal/g biomass)
<i>Bacillus subtilis</i> bacteria	Au	79
<i>Bacillus licheniformis</i> bacteria	Fe	45
<i>Aureobasidium pullulans</i> bacteria	Pb	220–360
<i>Citrobacter sp</i> bacteria	U	800
<i>Sargassum natans</i> algae	Au	400
<i>Chlorella vulgaris</i> algae	Au	80
<i>Sargassum natans</i> algae	Au	400
<i>Chondrus crispus</i> algae	Au	76
<i>Ascophyllum nodosum</i> algae	Cd	215
<i>Rhizopus arrhizus</i> fungus	Ag	54
<i>Rhizopus arrhizus</i> fungus	Au	164
<i>Streptomyces noursei</i> fungus	Ag	38
<i>Saccharomyces cerevisiae</i> fungus	Ag	5
<i>Saccharomyces cerevisiae</i> fungus	Cd	20–40
<i>Aspergillus niger</i> fungus	Au	176
<i>Penicillium chrysogenum</i> fungus	Cd	56

Membrane Biosorption, Table 2 The isotherms of biosorption equilibrium (Pagnanelli et al. 2003)

Isotherm	Equation
Langmuir	$q = q_{\max} \cdot \frac{b \cdot C}{1 + b \cdot C}$
Freundlich	$q = k \cdot C^{\frac{1}{n}}$
Langmuir–Freundlich	$q = q_{\max} \cdot \frac{b \cdot C^{\frac{1}{n}}}{1 + b \cdot C^{\frac{1}{n}}}$
Radke and Prausnitz	$\frac{1}{q} = \frac{1}{a \cdot C} + \frac{1}{b \cdot C^n}$
Redlich–Peterson	$q = \frac{a \cdot C}{1 + b \cdot C^n}$

Table 1) and rate of sorption (see Table 2). The smaller the particle size, the greater the surface areas and shorter diffusion paths for the molecules of xenobiotic (Koltuniewicz and Bezak 2002; Koltuniewicz and Witek 2004). Due to the special ability to bind heavy metals, biosorption process
